Psychological Bulletin

(Continued on inside back cover)

ISHED BIMONTHLY BY THE AMERICAN PSYCHOLOGICAL ASSOCIATION

The *Psychological Bulletin* publishes evaluative reviews and interpretations of substantive and methodological issues in the psychological research literature. The Journal reports original research only when it illustrates some methodological problem or issue. Discussions of methodological issues should be aimed at the solution of some particular research problem on psychology, but should be of sufficient breadth to interest a wide readership among psychologists; articles of a more specialized nature can be directed to the various statistical, psychometric, and methodological journals. The *Bulletin* does not publish original theoretical articles; these should be submitted to the *Psychological Review.*

Abstracts: All articles must be preceded by an abstract of 100–175 words. Detailed instructions for preparation of abstracts appear in the *Publication Manual of the American Psychological Association* (2nd ed.), or they may be obtained from the Editor or from APA Central Office.

Blind review: Because reviewers have agreed to participate in a blind reviewing system, authors submitting manuscripts are requested to include with each copy of the manuscript a cover sheet which shows the title of the manuscript, the name of the author or authors, the author's institutional affiliation, and the date the manuscript is submitted. The first page of the manuscript should omit the author's name and affiliation but should include the title of the manuscript and the date it is submitted. Footnotes containing information pertaining to the author's identity or affiliation should be on separate pages. Every effort should be made to see that the manuscript itself contains no clues to the author's identity.

Manuscripts: Submit manuscripts in triplicate to the Editor, R. J. Herrnstein, *Psychological Bulletin,* Harvard University, 33 Kirkland Street, Cambridge, Massachusetts 02138, according to instructions provided below.

Instructions to Authors: Authors should follow the directions given in the *Publication Manual of the American Psychological Association* (2nd ed.). Instructions on tables, figures, references, metrics, and typing (all copy must be double-spaced) appear in the Manual. Authors are requested to refer to the "Guidelines for Nonsexist Language in APA Journals" (Publication Manual Change Sheet 2, *American Psychologist,* June 1977, pp. 487–494) before submitting manuscripts to this journal. All manuscripts should be submitted in duplicate and both copies should be clear, readable, and on paper of good quality. Dittoed copies are not acceptable and will not be considered. Authors are cautioned to carefully check the typing of the final copy and to retain a copy of the manuscript to guard against loss in the mail.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1979: $40 domestic, $42 foreign, $7 single issue. APA member rate: $15. Write to Subscription Section, APA.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Dept., APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Published bimonthly (beginning in January) in one volume per year by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Washington, D.C., and at additional mailing offices.

Criminal Behavior of Discharged Mental Patients: A Critical Appraisal of the Research

Judith Godwin Rabkin
Epidemiology of Mental Disorders Research Unit
Psychiatric Institute, New York, New York
New York State Office of Mental Health

Continuing debate on the dangerousness of mental patients between mental health representatives and community members justifies a critical appraisal of the available evidence. Included for review are epidemiological, prospective studies of arrests and convictions among discharged mental patients in comparison to arrests and convictions of the general public and their change over time. Patients with arrest records prior to hospitalization were found to have arrest rates after discharge that far exceeded those of the general public or of other patients. As the number of patients with prior records has increased over time, postdischarge rates for patients considered as a single group have increased accordingly, although patients without prior records continue to have postdischarge arrest rates equal to or lower than those of the general public.

For at least 25 years, investigators of public attitudes toward mental illness have reported that most people dislike, distrust, and fear the mentally ill. Although it has become less socially acceptable to acknowledge such attitudes today, they continue to prevail (Rabkin, 1974, 1976). When these attitude studies were first conducted during the late 1940s and early 1950s, interest was motivated by the desire of mental health professionals to encourage troubled people to seek psychiatric help earlier in the course of their difficulties and to ease the reentry into the community of patients released from distant mental hospitals. More recently, as state and local mental health agencies have accepted the tenets of the community mental health movement and have adopted policies promoting community-based treatment, negative public attitudes about mental illness and mental patients have served as a real and persistent obstacle to the fulfillment of these goals. Communities resist the placement in hotels and boarding houses of older chronic patients discharged after years of hospitalization, often on the grounds that such ex-patients are unsupervised, uncontrolled, and unsuitable neighbors. At the same time, local treatment facilities for both chronic and younger acute patients are resisted for fear that additional mentally ill people will be attracted to the neighborhood, thus compounding the situation. Such resistance has been vocal, effective, and widespread, leading to the passage of municipal ordinances and legal barriers to the establishment of local facilities (Aviram & Segal, 1973; Segal &

Requests for reprints should be sent to Judith Godwin Rabkin, Epidemiology of Mental Disorders Research Unit, Psychiatric Institute, 722 West 168th Street, New York, New York 10032.

Avirām, 1976). It has been estimated that "for every community program that is established and continues to operate, another has been prohibited or closed because of community opposition" (Piasecki, Note 1). Clearly, community opposition continues to be a major problem for those charged with the task of opening new community facilities to treat the mentally ill and retarded.

Investigators have defined two major sources of apprehensiveness that seem largely to account for the pervasiveness and tenacity of public concerns: People perceive mental patients as both unpredictable and dangerous. Unpredictable behavior is always unsettling to social groups because order and stability are threatened. When people are identified as unpredictable, they lose credibility and social standing, and others eventually try to avoid them (Cumming & Cumming, 1965; Nunnally, 1961). However, the most influential factor behind negative attitudes is the perception of the mental patient as dangerous (Cocozza & Steadman, Note 2). This is the cornerstone of public apprehensions and a crucial stumbling block in communications between members of the public and representatives for mental health groups.

It is widely believed by community members that mental patients are likely to display impulsive, violent, assaultive, and otherwise socially disruptive behavior. In public meetings held to consider the applications of new psychiatric facilities in the neighborhood, many community speakers openly express such fears. The vast majority of mental health professionals respond by declaring that such fears are groundless, that mental patients are actually less likely to commit crimes than other people, and that the local opponents are speaking from prejudice rather than fact. Indeed, in such settings, speakers for the mental health establishment have become quite eloquent in condemning the uncharitable and reactionary attitudes of the communities that have expressed resistance to new psychiatric facilities.

Most mental health professionals do believe that mental patients have relatively few encounters with the law and that on the infrequent occasions when they are arrested, it is for the minor offenses such as vagrancy, loitering, or public intoxication. It is furthermore assumed that such charges stem largely from socially inept and unacceptable behavior like urinating on lampposts or wandering aimlessly in the street rather than from purposive criminal acts such as robbery. Psychiatric textbooks, general medical magazines (Farnsworth, 1977), and psychiatric reviews (Gulevich & Bourne, 1970) generally concur in their evaluation of the scientific literature on the criminal behavior of the mentally ill: This literature is regarded as sparse and inconsistent but is overall supportive of the position that patients commit fewer crimes than the general population. This seems to be the prevailing belief not only among mental health professionals but also among most educated, liberal, and thoughtful people.

Debate on these conflicting perceptions of the dangerousness of mental patients persists between mental health representatives and members of neighborhoods slated for the opening of psychiatric facilities. Neither side has resorted to examination of the available evidence, although much heat and controversy have been generated. Such a review seems appropriate and timely and is the object of the present undertaking.

The questions to be considered concern the prevalence of arrests among former hospitalized patients and former outpatients treated for psychiatric disorders in comparison to arrest rates of the general public. The separate literature on the prevalence of mental illness among criminals is not included, nor is a review of efforts to predict dangerousness among mental patients, criminal defendants, or the criminally insane. The studies included for review are epidemiological, prospective studies, and each is addressed to one or more of the following questions:

1. Do discharged mental patients currently have higher arrest rates than members of the general population? (a) Have these rates changed over time? (b) What factors have contributed to such changes, if observed?

2. What are the best predictors of postdischarge arrests?

3. What is the association between arrest risk and diagnostic category?

4. Are discharged mental patients more likely to be arrested for certain types of crime?

5. Does hospitalization reduce the probability of recidivism among patients with prior arrest records?

After a brief review of pertinent methodological issues, each study is presented critically in some detail. Studies are classified as *early* or *recent* and are reviewed in chronological order. Because it may be difficult to keep track of the details of several studies simultaneously, two tables have been prepared as an aid. Table 1 outlines the design of each study, and Table 2 presents selected results. Following presentation of the studies, cumulative findings are summarized according to the questions just posed, and the state of the evidence for each is evaluated. Finally, some implications are drawn with respect to the relevance of these findings for efforts to further develop community psychiatry programs.

Methodological Considerations

The question under consideration here is a deceptively simple one: Are formerly hospitalized mental patients engaged in criminal activity with lesser or greater frequency than other people? The appropriate research design is necessarily a prospective one [1] (sometimes called a cohort design): Two groups of people, one with a history of psychiatric hospitalization and one without but otherwise similar, are followed for equal periods of time to obtain for each group counts of police encounters, arrests, convictions, and incarcerations. Because it has been claimed that mentally disturbed citizens are treated differently by the criminal justice system than are other defendants, a retrospective or case-control design in which the histories of convicted offenders are searched for evidence of mental illness is not as effective, although it is considerably simpler and less costly. The current review therefore focuses on prospective studies.

Since arrests for criminal acts are comparatively rare events and because the expected incidence of arrests was unknown at the start, investigators were obliged to study a large number of people at risk. Among the studies reviewed, samples ranged from 310 to nearly 100,000 patients discharged from the same or similar hospitals within a 1- or 2-year time span. Frequency of arrests within a specified follow-up period ranging from $1\frac{1}{2}$ to $5\frac{1}{2}$ years was computed from police records, and then annual arrest rates were compared with figures compiled at the catchment area, county, state, or national level for the general population of similar age. Comparative rates of arrests for patients and the general population served as the basis for conclusions about the relative incidence of criminal activity among discharged mental patients.

A number of methodological problems become apparent in the course of reviewing studies in this field. Some problems, such as lack of equivalence in the demographic and psychiatric characteristics of patient samples, are more or less unavoidable when one considers together any series of studies conducted by different people in different places at different times. Moreover, such heterogeneity may be regarded as an asset in the sense that replicated findings can be generalized to a broader segment of the population of patients. Other difficulties, such as extrapolating rates based on few cases, are common to any epidemiological study of rare events and can be dealt with by collapsing categories to enlarge the number of cases used to generate rates and by seeking patterns rather than focusing on separate rates by specific category.

Apart from such general considerations, there are a number of problems specific to the field under study that warrant mention.

[1] The term *prospective* is used here in the sense advocated by Lilienfeld (1976) in which two groups, one with and one without a certain characteristic, are followed and rates of a subsequent disorder or event are computed for each. In this case, the two groups are hospitalized mental patients and some subset of the general public, and the events in question are arrest rates within a given follow-up period.

Table 1
Research Design of Studies of Arrest Rates of Discharged Mental Patients: Prevalence Period, Crime Categories, and Sample and Control Group Characteristics

Authors	Years of discharge	Prevalence period: Prior arrests	Prevalence period: Follow-up	Crime categories	*N*	Criteria for inclusion	Control population
Ashley (1922)	1912–1922	—	1 month to 1 year	All arrests	1,000	Patients on parole status from one state hospital	None
Pollock (1938)	1937	—	1 year	All arrests	5,833	All patients on parole status in 1937 from state hospitals	1937 arrests in New York State, over age 14
Cohen & Freeman (1945)	1940–1944	—	2 years	All arrests	1,676	Patients paroled or discharged between 1940–44 from state hospital	1942–1943 arrests for Connecticut residents
Brill & Malzberg (1962)	Fiscal 1947	Lifetime	5 years	All arrests	10,247	Male patients over age 15 discharged from New York State hospitals	1947 arrests for males over age 15 in New York State
Rappeport & Lassen (1965, 1966)	1947 and 1957	5 years	5 years	Five violent crimes only	1,401 in 1947 4,281 in 1957	Discharges from all hospitals (private, public, federal) in Maryland, over age 15	Maryland male and female population over age 15 for five crime categories
Giovannoni & Gurel (1967)	1956	—	4 years	All arrests and all encounters with police	1,142	Male VA hospital patients (95% schizophrenic) under age 60	U.S. residents in cities with over 25,000 people

Table 1 (*continued*)

Authors	Years of discharge	Prevalence period: Prior arrests	Prevalence period: Follow-up	Crime categories	*N*	Criteria for inclusion	Control population
Sosowsky (Note 3)	1966–1970	—	1–5 years	Homicide and assault convictions	99,361 hospital patients; 143,322 outpatients	California patients over age 15 receiving state mental health funds	California nontreated residents over age 15
Sosowsky (Note 3)	1972–1973	6 years	Not given	All arrests, convictions for homicide and assault	301	San Mateo residents over 15 discharged from state hospital (73% schizophrenic)	San Mateo County nonhospitalized residents over age 17
Zitrin, Hardesty, Burdock, & Drossman (1976)	1969–1971	2 years	2 years	All arrests	867	Residence in Bellevue catchment area, about half schizophrenic, aged 10–80 (most 20–50)	Catchment area population and all U.S. cities
Durbin, Pasewark, & Albers (1977)	1969	5 years	5 years	All arrests	461	All state hopsital patients aged 18–64 admitted in 1969 (70% alcoholics)	Wyoming population aged 18–64
Steadman, Melick, & Cocozza (Note 5)	1968 and 1975	Lifetime	19 months	All arrests	1,920 in 1968 1,938 in 1975	Systematic samples of discharged state hospital patients over age 17	New York State population over age 17

Note. VA refers to the Veterans' Administration.

One issue concerns the differential probability that mentally disturbed and other people will be arrested, sent to jail, convicted, and incarcerated. (Studies in this review excluded from consideration those defendants who were hospitalized by court order for psychiatric observation, as well as those classified as criminally insane.) It has been argued that convictions and even arrests are inadequate measures of crime among mental patients because the seriously disturbed defendant and those with histories of hospitalization are rehospitalized instead of arrested. Recent evidence supports this contention. Both Levine (1970) and Lagos, Perlmutter, and Saexinger (1977) found extremely high rates of violent or illegal behavior presented as part of the basis for hospitalization in the admission notes of randomly selected inpatients. Levine reported that 71 of 100 patients had com-

Table 2
Results of Studies of Arrest Rates of Discharged Mental Patients: Samples, Comparative Rates, Overrepresented Diagnostic Groups, and Most Common Offenses

Authors	Diagnostic and sex distribution of sample	Total arrests per 1,000: Patients	Total arrests per 1,000: General public	Arrests per 1,000 for assaults and homicides only: Patients	Arrests per 1,000 for assaults and homicides only: General public	Overrepresented diagnostic groups	Most common offenses
Ashley (1922)		37					
Pollock (1938)		6.9	98.5				
Cohen & Freeman (1945)		26					
Brill & Malzberg (1962)	Males only	12	49	1.3	.8	Alcoholics, drug abusers, psychopathic personalities	All felonies; assaults and homicides
Rappeport & Lassen (1965)	Males only						Robbery
Rappeport & Lassen (1966)	Females only						Aggravated assault
Giovannoni & Gurel (1967)	Males only; 95% chronic schizophrenics			3.27	.94		Violent crimes (27% of all arrests); drunkenness (23% of all arrests)
Sosowsky (Note 3)	Statewide sample			2.96[a]	.43[a]		
Sosowsky (Note 3)	San Mateo County sample; 73% schizophrenics			27.8 11.7[a]	1.8 .41[a]		Violent crimes (17% of all arrests)
Zitrin, Hardesty, Burdock, & Drossman (1976)	47% schizophrenics			7.3	1.59 (U.S.) 6.26 (local)	Alcoholics and addicts (schizophrenics had excess rates for violent crime with bodily harm but not for total arrests)	
Durbin, Pasewark, & Albers (1977)	Male rates only; 69% alcoholics			3.0[b]	1.6	Addicts and personality disorders	Drug offenses
Steadman, Melick, & Cocozza (Note 5)	1968 discharge sample; 27% schizophrenics	73.5	27.5	5.6	2.3	Personality disorders and substance abusers	Drug, property, and violent crimes
Steadman, Melick, & Cocozza (Note 5)	1975 discharge sample; 32% schizophrenics	98.5	32.5	12.0	3.6	Paranoid states and personality disorders	Property, sex, and violent crimes

[a] Conviction rate.
[b] By arrests, not persons.

mitted illegal acts, including 23 acts judged to be felonies, in the course of episodes leading to their hospitalization, none of which were prosecuted. Similarly, Lagos and his colleagues found that 36% of 321 patients manifested some form of violent behavior in the episode leading to hospitalization, of whom only 2.6% were prosecuted. Despite validity problems in these data sources, including the possibility that admitting personnel unduly emphasize violence to justify the decision to admit, it does seem that many dangerous, violent, and illegal acts committed by distressed and distraught people lead to hospitalization rather than arrest. As a result, arrest rates may underestimate frequency of violence among the mentally ill.

Another source of error in use of arrest and conviction rates to represent frequency and type of illegal behavior of the mentally ill concerns the response of the criminal justice system. If indeed charged instead of hospitalized, the disturbed defendant may be acquitted on grounds of insanity. Further, the charge may be reduced. In some states, defendants accused of serious crimes (felonies) cannot be committed to a psychiatric hospital except for brief observation if an insanity plea is under consideration. A common solution is the reduction of a charge to a lesser offense (a misdemeanor) to enable civil commitment of a disturbed defendant (Paull & Malek, 1974). This procedure applies only to psychotic individuals; sociopathy, alcoholism, and drug abuse are not legally acceptable grounds for either acquittal or reduction of charges for commitment purposes. One result is the lowering of overall arrest rates for the mentally ill. Another is the reduction of the severity of charges pressed against schizophrenics, who then appear less prone to criminal acts than nonpsychotic diagnostic groups.

In an effort to obtain less biased measures of criminal activity of mental patients, one may seek to enumerate all police contacts rather than just those culminating in arrests. Apart from the practical difficulties of obtaining such information, however, one cannot equate police contact with criminal activity. First, most police contacts do not lead to arrests. The Federal Bureau of Investigation (1976) indicated that only 21% of index crimes[2] were cleared during 1976. A crime is *cleared* when law enforcement agencies have identified the offender, have sufficient evidence to charge him or her, and have actually taken him or her into custody. Clearance rates vary widely by type of offense, ranging from 79% of murder offenses to 14% of motor vehicle thefts. Police clear a high percentage of crimes against the person, both because of the more intense investigative effort made and because of the greater availability of witnesses to identify the perpetrator and to testify against him or her. In their review of dispositions of encounters between discharged mental patients and the police, Giovannoni and Gurel (1967) also found that only a minority of police encounters culminated in arrests. Although such low clearance rates reflect to some extent limitations of law enforcement resources and procedural constraints, they are necessarily less than 100% because several people may be suspected in the same case and only one is ultimately charged.

Another objection to the use of police contacts as an index of criminal activity is the possibility of differential "whistle blowing" behavior for ex-mental patients and other citizens. Former patients may be more likely to be under police surveillance because of their known status; their social ineptnesss may heighten their visibility, or unfriendly neighbors may call the police with complaints for purposes of harassment. A more basic difficulty is the definition of criminal activity, which is necessarily determined only by a judge in court, so that police contacts may be interesting to study, but are insufficient evidence in themselves.

A similar argument may be made with respect to arrest records. Here also, the de-

---

[2] Index crimes include seven offenses selected because of their seriousness, frequency of occurrence, and likelihood of being reported to the police. They are murder, forcible rape, robbery, aggravated assault, burglary, larceny–theft, and motor vehicle theft. The Federal Bureau of Investigation's annual national reports refer to these seven crimes only.

fendant may be innocent. However, it seems likely that a sufficient number of mental patients are taken out of court channels before completion of a trial and passage of a verdict so that use of conviction rates alone gives a misleadingly low estimate of the criminal activity of the mentally ill (Zitrin, Hardesty, Burdock, & Drossman, 1976). In all of the studies reviewed here, with one exception, measures of criminal behavior were based on arrest rates. The exception, a pair of studies conducted by Sosowsky (Note 3), found conviction and incarceration rates highly correlated with arrest rates.

Another problem concerns computation of crime rates by specific category. There is no national criminal code, and definitions and classifications of offenses vary between jurisdictions and over time within a given jurisdiction. A particular offense may be a felony in one state and a misdemeanor in another, or it may be reclassified as one or the other 5 or 10 years later. It is therefore difficult to compare arrest rates, for example, for concealed weapons between Wyoming and New York. One solution is to consider broader categories of crime rather than specific offenses, although here the problem becomes what system of classification to use in developing such categories. It may be to circumvent such difficulties that the majority of recent investigators chose to emphasize the relative occurrence of violent crimes, defined as homicides plus assaults, in which the charges are less ambiguous, the proportion of arrested perpetrators is comparatively high, and the task of classification is less difficult.

The foregoing issues are related to the task of defining and counting cases, the results of which constitute the numerator of a rate. There are also problems in selecting an appropriate denominator, which is defined as all cases at risk for the event in the numerator. Almost all investigators have computed the denominators of their patient rates as the number of discharged patients in their sample. Because of the large sample sizes used in most studies, the size of error in using this denominator is probably minor, especially if the sample is not broken down into subgroups. However, some patients die, move to other states, or spend time away from the community in jails, mental or medical hospitals, nursing homes, or elsewhere. In each instance, they are no longer "at risk" for arrest. In only one study (by Giovannoni & Gurel, 1967) was an effort made to determine the actual population at risk; others overestimated the denominator size and thus obtained lower arrest rates. Another prevalent error is the inclusion of patient arrests in general population figures derived from Federal Bureau of Investigation (FBI) records. Only Sosowsky (Note 3) excluded treatment patients from his population arrest rates.

An additional source of error is lack of genuine equivalence between patient and general population groups. No one has ever claimed that state hospital patients (who constitute the vast majority of patients studied in this field) are representative of the general population. At best, they represent the less fortunate members of society who may be collectively described as lacking social status, financial resources, occupational skills, and often family ties. If mental patients in public facilities were compared to their peers in these terms, each of which is associated with the distribution of both arrests and mental illness in the general population, fewer differences might be found.

Although it is true that studies in this research area are individually and collectively incomplete and in many respects insufficient in their designs and analyses, their review appears warranted on several grounds. First, they represent the only available empirical evidence in an area of tremendous public concern. At the present time intense policy debates are being conducted regarding the relative rights of patients and of communities into which they are discharged. The cumulative evidence that is derived from these studies may help to clarify major elements in these debates. In addition, summarization and criticism of this literature should serve as a guide to future research by indicating important, unresolved questions and suggesting more fruitful methods for their investigation.

In my opinion, the methodological issues raised here are both relevant and significant,

but are probably not major sources of weakness in the group of studies to be reviewed. The direction of bias is not consistent. Although no study is flawless, no problem is universal, so that agreement of results across studies lends robustness to their conclusions, the foregoing difficulties notwithstanding.

Literature Review

Early Studies [3]

Between 1922 and 1955, four studies were conducted regarding the subsequent arrest rates of paroled or discharged mental patients. These studies have been accepted uncritically and quoted extensively during the past 50 years to substantiate the prevalent belief that mental patients are less dangerous and less inclined to criminal activity than other people.

In 1922 the superintendent of the Middletown State Homeopathic Hospital in New York State published a brief report describing the subsequent careers of 1,000 patients paroled from his hospital during the previous 10 years (Ashley, 1922). Ashley noted that "as the parole period up to three years ago covered only a period of from one to six months the data are not as complete as might be desired" (p. 64). This passage is quoted to show the basis for computation of period prevalence rates, which is evidently not entirely clear. The length of parole during the last 3 years of the study was not reported, nor was the distribution of paroles over time. Assuming an equal distribution and using the mean parole duration, one is led to conclude that the report was based on a 3-month follow-up for 700 of the 1,000 cases. Later publications referring to a 1-year parole period serve as the basis for the conjecture that the parole period during the last 3 years of Ashley's study did not exceed 1 year.

Ashley carefully tallied recovery rates, discharge status, economic status, social adjustment, and readmissions of his 1,000 parolees, of whom two thirds were female. Sixty-four percent were either partly or fully restored to their former social roles, including the 46% that were recorded as cured. Although nearly one quarter of the parolees were involved in social conflicts serious enough to be brought to the attention of the hospital authorities, only 12 were arrested. The source of arrest figures is not given, but it seems likely that they were obtained from reports of relatives or neighbors to parole officers. The 12 arrests were for offenses including "vagrancy, assault and battery, forgery, swindlery or profiteering" (p. 65).

Twelve arrests for 1,000 patients during a mean time period of 3 months after hospital release would be equivalent to an annual rate of 37 per 1,000.[4] Another 223 parolees were reported in Ashley's words to have engaged in "antisocial acts either resulting from or conducive to further mental trouble" (p. 65), but they were not arrested. One may conjecture that only 12 of 235 known antisocial acts resulted in arrest because of the accessibility of parole officers as negotiators or problem solvers or because of the reluctance of others to press charges against parolees. Arrest rates for the general population of that time were not reported, so one cannot determine the extent to which the observed rates depart from expected rates.

Two other points regarding Ashley's arrest figures warrant consideration. First, two thirds of his sample were female, and women's arrest rates historically have been much lower than men's. In addition, parole status is not the same as the unconditional discharge of

---

[3] For the reader's convenience and to facilitate comparisons, all rates cited here are expressed as per 1,000 even if the authors used a different basis.

[4] The rate of 37 per 1,000 is derived by estimating that 70% of the sample had a mean follow-up of 3 months and the rest a mean follow-up of 1 year. Thus, 70% of 12 was multipled by 4 to give an annual basis and then added to the remaining 30% ($70\% \times 12 = 8.4 \times 4 = 33.6 + 3.6 = 37.2$). This estimate is vastly greater than the rate computed and reported by Pollock (1938) in his article that summarizes Ashley's (1922) findings and that has since been widely quoted. Pollock interpreted the passage cited above to mean that Ashley's cases "were under observation on the average nearly 5 years," yielding an "average annual rate of arrests . . . of 2.4 per 1,000" (p. 239). Unless Pollock had access to additional information from Ashley other than the 1922 article, which Pollock does not mention, it would seem that his estimate is based on a misreading of Ashley's article.

contemporary patients. Parole could be revoked by the unilateral decision of hospital representatives, so patients may have been more careful about their behavior and more closely supervised by family members than patients described in recent studies.

In 1938, Pollock published a study of the legal offenses committed by patients paroled during fiscal 1937 from all New York State hospitals. At that time, patients considered eligible for release were paroled for 1 year before discharge. "To be deemed eligible for parole, the patient must be harmless, tractable, and able to mingle with others without causing trouble. . . . No patient is placed on parole unless there is a safe and suitable home to receive him and a relative or friend to welcome and care for him" (p. 241). Evidently patients were rigorously screened before their parole in terms of social as well as psychiatric criteria.

Pollock wrote his article to counteract the "frequently made charge that the paroling of mental patients by State hospitals is a dangerous procedure" (p. 236), and his data certainly look convincing although their sources are ambiguous. In 1937, nearly 65,000 patients were distributed among the 20 state facilities, and on an average day there were 5,833 patients on parole, including a slight excess of males. Pollock reported that paroled patients were arrested for 40 offenses, including 29 misdemeanors and 11 felonies; all but 3 of the misdemeanors were committed by men. Dividing 40 by 5,833, he obtained an arrest rate of 6.9 per 1,000. Unfortunately, Pollock did not indicate the source of his arrest data or the time period covered. Since this rate is compared to that of the state's general population in 1937, the implication is that the 40 arrests were all those committed by all patients paroled during fiscal 1937. Accordingly, this rate is substantially lower than that of the general public over 14 years of age in New York State, which was 98.5 per 1,000 in 1937[5] or 14 times higher than the arrest rate of paroled patients. As Pollock put it, whereas 40 arrests were made among parolees, 576 arrests were made among an average normal group of like size in the general population.

Pollock cited, as further evidence of the arrest rate of parolees, a 10-year follow-up study of 741 patients paroled from two New York State hospitals conducted under the direction of R. Fuller and apparently never published. In his one-paragraph summary of the findings, Pollock reported that "among the 289 male patients there were 19 arrests and among the 452 female patients five arrests. The annual rate of arrests among males was 0.7% and among females 0.1%" (p. 240). No further information was provided.

Pollock attributed these low arrest rates to two factors: the extreme care exercised in screening patients for parole and their constant surveillance while on parole. Not only did social workers regularly visit the patients to interview them as well as their families but patients were required to attend parole clinics at specified intervals. When the parole officer thought it necessary, the patient was fetched by the hospital car and promptly readmitted. Pollock concluded that "the hospital methods are well planned and are producing beneficial results to the patients and communities served" (p. 242). The only reason to entertain some doubt about his figures, which as indicated are undocumented, is his treatment of Ashley's annual arrest rates (discussed earlier).

Like Ashley and Pollock before them, Cohen and Freeman (1945) were associated with a state hospital and were distressed by public resistance to the presence of discharged mental patients in the community. They were eager to promote patient acceptance by showing that they were not dangerous and toward this end conducted a follow-up study of 1,676 patients who were paroled and discharged from one of three state hospitals in Connecticut between 1940 and 1944. (This is the only early study not based on New York State patients.) Patients were followed for an average period of 2 years during which 87 or 5.2% were arrested, yielding an annual arrest rate of 26

[5] This is a peculiarly high figure compared to general population arrest rates subsequently reported (1947 through 1975), which are never more than half as high.

per 1,000. It occurred to Cohen and Freeman that patients who were in trouble with the law after discharge might also have police records before their hospitalization. They found that 314 or 18.4% of their patients had such prior records, and all but 6 of the patients arrested after discharge came from this group. In other words, patients without prior arrest records were almost never in legal difficulty after hospital discharge, whereas 93% of those subsequently arrested had records. Both before and after hospitalization, more than two thirds of arrests were for "drunkenness and breach of peace." Excluding sex offenses for which no population rates were available, the total annual felony rate per 1,000 for discharged patients was .9, compared to a rate of 13.7 per 1,000 for the general population. From these figures Cohen and Freeman concluded that "these patients who have left mental hospitals are not as dangerous to the community as those who have never been judged mentally ill" (p. 699).

Cohen and Freeman considered the etiological significance of mental status in the production of criminal behavior but reached no firm conclusions. They suggested that some arrests seem related to mental illness and that "once the patient is hospitalized and released, the arrest-precipitating behavior is either no longer present or is under some social control," (p. 699) referring in the latter point to control by other people. On the other hand, they felt that many of their recidivists were "inadequately adjusted for reasons which are not directly related to their mental illness at all. . . . [They] seem merely to have been following old anti-social patterns" (p. 700). In subsequent literature reviews such as that by Rappeport, Lassen, and Hay (1967), their idea that hospitalization produces a reduction in criminality is emphasized, but the notion of coexisting patterns of mentally ill and antisocial behavior is overlooked.

The next, and perhaps most influential, study in this series of early investigations was conducted for the New York State Department of Mental Hygiene by Brill and Malzberg (1962). Their report, based on state hospital discharges during fiscal 1947, was circulated within the department in 1954 but was not otherwise disseminated until 1962. Even then, it was distributed in the form of a supplementary mailing by the American Psychiatric Association rather than published in a standard journal. Nonetheless, it became widely known and often cited, both because of its large scope and because of its investigation of historical variables associated with arrest rates as well as of the rates themselves.

In their work, Brill and Malzberg studied the arrest rates of 10,247 male patients over age 15 released from New York State mental hospitals during fiscal 1947. Arrests at any time before and for 5½ years after hospital release were traced by means of a fingerprint registry in Albany for approximately half the sample.[6] Arrest rates for patients were compared with those of all males over age 15 in New York State for 1947.

Patients were divided into two categories: those with a prior history of arrests and those without. Arrest rates after hospital release were computed for both groups separately and together. The patients with prior arrest records (15%) turned out to have dramatically higher subsequent arrest rates than the other patients as well as than the general population, whereas the patients without arrest histories (85%) had considerably lower rates than the general population for misdemeanors, all felonies, crimes of violence, and all crime categories combined. When the patients were considered together as a single group, their felony arrest rates were higher and their total arrest rates were lower than those of the general population.

As seen in Table 3, the patients fall into two very different groups depending on arrest history. As a group, patients with prior arrests had subsequent arrest rates ranging from 6 to 8 times higher than those of the general population and 9 to 16 times higher than those of the other patients. Although

[6] These patients ($N = 5{,}354$) were admitted after fingerprinting became a routine part of the admissions procedure. Arrest rates for the remaining 4,893 were calculated based on demographic and historical characteristics.

Table 3
Annual Arrest Rates per 1,000 for Male Patients Released From New York State Hospitals and for the General State Population in 1947

Offense	Patients with arrest records	Patients without arrest records	Total patients	General population
Misdemeanors	32.8	2.0	6.7	45.8
Felonies (all)	26.3	1.6	5.5	3.3
Homicides and assaults only	5.3	.6	1.3	.8
All categories	60.0	3.6	12.2	49.1

Note. These data are from Brill and Malzberg (1962).

constituting only 15% of the patient group, their excess of arrests in the felony category, especially for violent crimes (homicide and assault), was sufficient to influence the arrest rate of all patients combined compared to that of the general population. This excess was due to only one third of the patients with prior arrests; 66% of these patients and 98% of the other patients were not arrested after hospital release.

A critical issue that Brill and Malzberg made some effort to address, which has not been dealt with by other investigators either before or since, is whether the recidivism rate among ex-convicts who have been in psychiatric hospitals is the same, lower, or higher than that of people with arrest histories who have not been hospitalized. Based on information from unnamed "expert criminologists," Brill and Malzberg reported an overall annual rearrest rate of 5% among paroled ex-convicts, which is similar to the 6% rate among released mental patients with arrest records. The unnamed experts also reported that only 5% of the general population in 1947 had arrest records, in contrast to 15% of the patient population.

Brill and Malzberg also looked into the demographic and psychiatric characteristics of patients in relation to arrest patterns. Overall, the same factors associated with recidivism in the general population were found to characterize rearrested patients, including unmarried status, youth, alcoholism, drug addiction, and residence in delinquency areas. Rearrested patients were overrepresented in the diagnostic categories of alcoholism, drug abuse, and psychopathic personality and significantly underrepresented among the major functional psychiatric disorders. Symptom severity and length of hospital stay were negatively correlated with recidivism. As one might expect, lower arrest rates prevailed among voluntary admissions. Brill and Malzberg concluded that "statistically the group of previously arrested patients behaves more like a segment of the correctional population than a primarily psychiatric one" (p. 7).

In summary, their data show that mental illness and psychiatric hospitalization do not raise the probability of subsequent arrest above that existing before hospitalization and do not create such a tendency if it did not previously exist. This is an observation of major and enduring significance, and it is perhaps ultimately all that must be said on the subject of crime and mental illness. Their data demonstrate that crime rates for ex-patients without arrest records are lower than those for the general population and are inflated by the presence of patients with police records. In 1947, and as one sees even more so today, men with arrest records constitute a larger proportion of the patient population than of the general population, and it is this that contributes to the higher arrest rates of mental patients when they are considered as one group.

The preceding four studies (sometimes counted as five when the paragraph about Fuller's findings, cited in Pollock, 1938, is considered separately) together constitute the foundation for psychiatric reassurances that former mental patients are no threat or danger to their neighbors. In fact, the first two studies concur in their results and interpretations, whereas the third and fourth identify the major factor contributing to higher arrests

among discharged patients, providing a framework within which to integrate the apparently contradictory findings of studies published before and after 1965.

The first three studies are difficult to evaluate because so little information is provided with respect to record sources, case representativeness and selection, and computation of rates. Nevertheless, even if the authors minimized patient arrests and used high estimates of population arrest rates to yield an exaggerated contrast, it is reasonably certain that mental patients discharged before World War II were less often arrested than were members of the general public.

Recent Studies

Since 1965, eight American studies including nine samples were designed to contribute further empirical evidence to the question of the dangerousness of discharged mental patients. Each study found that arrest or conviction rates of former mental patients equaled or exceeded those of the general population in at least some crime categories when patients were considered as a homogeneous group. Although each study has some limitations and all do not provide equivalent data, they are cumulatively persuasive in their evidence that patterns of arrests among former mental patients are very different from and far higher than those reported earlier, both in absolute terms and in comparison to the general public.

In terms of temporal sequence, the studies of Rappeport and Lassen (1965, 1966) serve as a bridge between the earlier studies and contemporary ones, since they investigated arrest rates of patients discharged during the fiscal years of 1947 and 1957 from all Maryland psychiatric hospitals. Findings for men and women were published separately (in 1965 and 1966, respectively). Rappeport and Lassen used a data set superior to data sets of other studies in that it included discharges from federal and private as well as state facilities. The total sample consisted of 708 men and 693 women in 1947 and 2,152 men and 2,129 women in 1957. Arrest records for 5 years preceding and 5 years following hospital discharge in 1947 and 1957 were collected from each police jurisdiction in the state. Comparative arrest rates for the state population for equivalent time periods were obtained from the FBI for males and females over age 15 separately.

Arrests were recorded for only five offenses, all of which were violent crimes against persons: murder, negligent manslaughter, rape, robbery, and aggravated assault. The obtained arrest rates are thus not comparable to *total* arrest rates reported in other studies. Further, they counted arrests only in the 5 years preceding this hospitalization rather than during the lifetime of the patient, as in the Brill and Malzberg (1962) study.

For each of the five crime categories, patient rates were equivalent to or higher than those of all Maryland residents. Male rates for robbery and female rates for aggravated assault were particularly high. Arrest patterns were not notably different between 1947 and 1957 for either males or females, despite expectations that newer treatment techniques would have reduced posthospitalization arrests. The authors drew two major conclusions. First, they found no support for the contention that mental patients "are to any great extent less involved in criminal behavior than those in the general community" (Rappeport & Lassen, 1965, p. 779). Second, they concluded, as did Brill and Malzberg, that recidivism among patients with histories of prior arrests is "not unlike that seen in the general community" (p. 779). In summary, they observed that "we as psychiatrists may be biased when we malign others for suggesting that some of our patients represent a threat to the community" (p. 779).

Rappeport and Lassen attempted to analyze arrests by diagnostic category; thus for each of the four time periods studied (before and after 1947 discharges and before and after 1957 discharges) they tallied arrests by diagnostic category. The two categories that accounted for the largest proportion of arrests in all four time periods were those of alcohol intoxication and schizophrenia. Since Rappeport and Lassen did not say how diagnoses were distributed in the entire sample, one cannot determine whether these diagnoses are underrepresented or overrepresented in the

subset of patients who were arrested. Further, only percentages were reported, which can be grossly misleading, as in the breakdown for females arrested after their 1947 release. The authors showed in tabular form that 33% of arrested females were diagnosed as manic-depressive, 33% as neurotic, and 33% as mental defective. In the footnote of another table they stated that only three arrests were made of female patients during this time period, so that the diagnostic categories each contain a single case.

These lacunae are partly offset by the presentation of arrest rates per 100 within diagnostic category for each of the four time periods. In these tables and in the text the misleading effects of the previous presentation of percent arrests by diagnosis are diminished, as one can see that the arrest rates per 100 for both alcohol intoxication and schizophrenia no longer appear outstanding, and that in fact no consistent association between arrest rate and diagnosis emerges across the four time periods. Some effort at statistical analysis would have been helpful in this context. As presented, this material may have some utility in defining patterns within the data set, but it is not otherwise informative.

Analyses by type of crime are also of doubtful value in Rappeport and Lassen's studies (1965, 1966), since in several categories the number of events was so few that the reliability of computed rates must seriously be questioned. For example, no more than two arrests for murder by male patients were recorded in any single time period; consequently, estimation of rates per 100,000 based on such rare occurrences is misleading because of the high probability of error. However, the cumulative rates for all five crime categories combined are based on sufficient numbers to be relatively stable, and the authors' conclusions seem reasonable and justifiable.

The next study, by Giovannoni and Gurel (1967), is distinguished by the national distribution of the patients studied, its exceptionally comprehensive pursuit of patients' status at follow-up, its restriction to the single diagnostic category of chronic schizophrenia among males, and its analysis of all police contacts and their dispositions, not only those that ended in arrests. Unlike any other researchers in this field, Giovannoni and Gurel computed arrest rate denominators by meticulously measuring "in-community days" and thus precisely determining the number of patients at risk for arrest in a given period of time. Unfortunately, criminal records preceding hospitalization were not reviewed, so that recidivism, which others have regarded as a major component of postdischarge arrest rates, could not be measured.

Giovannoni and Gurel studied the subsequent arrest records of 1,142 males under 60 years of age, 95% of whom were chronic schizophrenics who were released from Veterans' Administration hospitals in 12 states during 1956 and who remained out of the hospital for at least 30 consecutive nights. For each patient, days spent in the community were computed by subtracting from the total those days spent in penal or psychiatric facilities. Follow-up information was gathered from periodic interviews as well as from institutional records. Outcome data consisted of all "socially hazardous" incidents in which patients were involved with police and not only those leading to arrest, since the authors were interested in seeing how often ex-patients who violated the law were rehospitalized rather than arrested.

During the 4-year follow-up, 156 of the 1,142 patients were involved in 192 offenses. In 48% of the incidents, the patient was sent to jail; of these patients, 40% were rehospitalized either directly or after a brief stay in jail. In 12% of the incidents other actions were taken including fines, probation, and dismissal. In the absence of a similar analysis of incident disposition of nonpatient police encounters, one cannot be sure that use of arrest rates alone underestimates the number of incidents in which patients were involved, but these figures suggest such a likelihood.

Offenses were analyzed by type, and rates for each type were compared to an average of national rates from 1957 to 1960 for cities with over 25,000 people, obtained from FBI records. It was necessary to use national figures despite their known limitations because the patients had distributed themselves

Table 4
Conviction Rates per 1,000 for Violent Crimes in California in 1971

Offense	Former state hospital patients	Former outpatients in county program	Nontreated state population over age 15
Assault	1.96	2.57	.33
Homicide	.98	.20	.10
Total no.	99,361	143,322	13,982,155

Note. These data are from Sosowsky (Note 3).

throughout the country. When offenses were grouped into crimes against persons, property, and morals, crimes against persons accounted for twice as many incidents (27%) as did crimes against property (12%). Another common offense was drunkenness. This is not surprising because two thirds of those arrested were rated as problem drinkers by interviewers. Since one is not told how many of the patients who were not arrested were also rated as problem drinkers, it is not clear whether problem drinking is a useful predictor of arrests in this chronically ill population; but in Giovannoni and Gurel's (1967) study, problem drinking seems to be a common characteristic of patients who were arrested.

Estimated annual rates of offense were computed by crime category for patients and compared to general population rates. Despite the low average annual number in each category (ranging from zero to two), which raises serious questions about the reliability of each of the rates, an overall pattern of differences between patient and general population rates emerged that seems more substantial and suggests true underlying differences. Patient rates were higher (compared to the general population) for several violent crimes against persons (homicide, aggravated assault, and robbery but not forcible rape) and much lower for crimes against property (petit and grand larceny, burglary, and auto theft). For example, the estimated annual rates per 1,000 for homicide were .99 for patients and .05 for the general population, whereas burglary rates for patients were .65, compared to 5.1 for the general population.

These findings are of interest first because the patients were chronic schizophrenics, a category infrequently associated with arrests and convictions in other studies. Second, the patients were discharged from 12 different hospitals that varied in the rigor of their discharge criteria among other things, and they were arrested under the laws of many states, ruling out these two factors as possible explanations for the obtained results. These findings are not congruent with those of Rappeport and Lassen (1965, 1966) concerning arrest rates by specific charge within the category of violent crime, but both studies show cumulatively high arrest rates for crimes against persons committed by discharged mental patients compared to the general population.

The California State Department of Health sponsored two studies of crime and mental illness that were conducted by Sosowsky (Note 3). He first undertook a statewide study of arrest, conviction, and incarceration rates for violent crimes (homicide and assault) of former state hospital patients and outpatients at state-supported facilities compared to the nontreated population of California. In the second study he reviewed the criminal records of a cohort of state hospital patients in San Mateo County (California) and compared their arrest and conviction rates with those of the nonhospitalized county population in 1974.

In the first study, Sosowsky listed all patients over age 15 who received California mental health funds (inpatient and outpatient) between 1966 and 1970 and matched them against the names of those convicted in the state for homicide and assault in 1971. Conviction rates were computed as shown in Table 4.

As the author noted, these rates did not take into account ex-patients arrested and ex-offenders treated in other states or those patients not at risk for becoming offenders because of death or movement out of state, but in view of his sample sizes these factors are probably insignificant. His results show that former patients are convicted at a significantly higher rate than are the nontreated population. Combining the two categories of offense, ex-hospitalized patients' rates were seven times and outpatient rates six times greater than those of nontreated California residents. Analysis by age and sex showed this excess to be true for all age groups and both sexes, especially for those under 20 and over 50. Female excess was even greater than that of males compared to the nontreated general population, although male rates for both patients and nonpatients were higher than equivalent female rates in absolute terms.

In his second study, Sosowsky analyzed arrests and convictions of 301 San Mateo County residents admitted to state hospitals between June 1972 and December 1973. The sample included over 95% of all patients that lived in San Mateo County who were admitted to state psychiatric facilities during this period. State criminal justice records were searched for all arrests and convictions of these patients from 1966 through 1973. It seems likely that most arrests preceded hospitalization, since the admission period fell at the end of the 8-year criminal record survey. In fact, 28 patients were still hospitalized when data analysis was begun in March 1974.

Patient arrest and conviction rates were computed for all offenses and for violent and nonviolent offenses separately. Violent offenses included those involving direct bodily harm (murder, assault, and rape) and potential for harm (robbery, burglary, crimes against children, threatening violence, possession of burglar's tools or weapons, kidnapping, arson, and rioting). Nonviolent offenses included all misdemeanors except violations of the motor vehicle code. Patient arrest and conviction rates were compared to those of the nonhospitalized San Mateo County population during the same time period. This is the only study in which the nontreated rather than the total—nontreated plus treated—population was used as a comparison group.

Of the hospitalized patients studied, 67% were male, most were between the ages of 20 and 39, 21% were nonwhite, and 73% were diagnosed as schizophrenic. Compared to the county's general population, males, nonwhites, and those in the 20–40-year-old age range were considerably overrepresented. A total of 47% of the patients were arrested at least once between 1966 and 1974, either before, after, or both before and after hospitalization. On the average, each patient was arrested 3.6 times over the period surveyed. Of the total group, 23.6% were charged with a violent offense and 23.6% were charged with a nonviolent offense (misdemeanor) only.

Since the variables of age, sex, and ethnicity are each independently associated with higher arrest rates in the general population according to FBI findings (e.g., Federal Bureau of Investigation, 1976) and since the patients were disproportionately young, male, and black, the sample was predisposed toward higher arrest rates than those of the general public. However, Sosowsky analyzed arrest rates for violent crimes within these categories, and patients continued to have much higher rates than their age, sex, and ethnic counterparts in the general population. For example, black male patients had an arrest rate of 6%, compared to 2.5% for black males in the county population. Patient excess therefore cannot be accounted for by skewed distributions of demographic variables.

In a subsequent analysis (Sosowsky, 1978) of the second study, Sosowsky raised the issue of the relation between diagnosis and crime category. He presented a table showing that 73% of the sample were schizophrenic, whereas 80% of patients arrested for violent offenses were so diagnosed. In contrast, only 70% of patients arrested for nonviolent offenses were schizophrenic. In the absence of statistical analysis, the very appearance of this table suggests a meaningful relationship between diagnosis and arrest category, but in fact these differences are not statistically significant (using a chi-square, the probability of the first distribution is .16 and that of the second is .45).

After analyzing arrest rates for all offenses combined, Sosowsky (Note 3) compared rates of arrests and convictions for the violent crimes of homicide and assault taken separately, for patients and for the county population. He found an enormous excess among the former. Patient arrests were 15 times higher and conviction rates 29 times higher than equivalent rates for the county population. Computed as rates per 1,000 for arrests and convictions, the arrest rate of patients was 27.80, compared to 1.80 for the county population. The patient conviction rate was 11.70, whereas the county population conviction rate was .41.

Together, Sosowsky's studies (Note 3) offer powerful support for the proposition that both outpatients and hospital patients in state-supported facilities have higher arrest and conviction rates for violent crimes than do nontreated California residents, and presumably, the general public. Unfortunately, these data do not contribute to an understanding of the causal direction between mental illness and crime because Sosowsky did not classify arrests in terms of whether they preceded or followed psychiatric hospitalization. He also did not analyze the recidivism rates of discharged patients with prior arrest histories. Thus, although the magnitudes of the arrest rates he reported for patients are impressive, they are difficult to interpret and they cannot be used to understand the relationships between the criminal justice and mental health systems or between criminal and disordered behavior.

The investigation of patient arrest rates conducted at Bellevue Psychiatric Hospital in New York City by Zitrin et al. (1976) achieved a certain notoriety even before it was published. After its presentation at a psychiatric meeting, a local organization concerned with the rights of mental patients threatened to bring suit against the authors on the grounds that their intent from the start was to discredit patients and to promote their involuntary detention in hospitals.

Zitrin and his colleagues studied 867 male and female patients admitted to this acute-care municipal hospital between July 1969 and July 1971 who lived in the hospital's catchment area (14th to 42nd Streets in Manhattan). Arrest records were located for each patient for the 2 years preceding and following this admission. The patient sample included a slight majority of males and an age range of 10 to 80, although over three quarters were between age 20 and age 50. Multiple hospitalizations were common; the 867 patients had a total of 2,000 admissions to Bellevue during the 2-year study. One patient was admitted 22 times. The authors reported that nearly half of the patients were diagnosed as schizophrenic, 7% as alcoholic, 6% as drug dependent, 8% as neurotic, and 32% as other. However, the diagnostic picture was often blurred, and there were notable overlaps between the categories of schizophrenia and substance abuse. For example, of the 42 patients with a primary diagnosis of schizophrenia who were among the 85 patients arrested for crimes of violence, 20 had a history of drug abuse, 8 had been drug dependent and alcoholic, and 2 others had previously been diagnosed as drug addicts. In other words, three quarters of the patients labeled schizophrenic in this subgroup previously were identified as substance abusers. Similarly, of the 10 alcoholics arrested for violent crimes, 4 had been diagnosed as schizophrenic on at least one previous occasion, and 1 was a drug addict. Evidently, at least among mental patients arrested for violent crimes, the boundaries between these three diagnostic groups (schizophrenia, alcoholism, and drug dependence) are fluid, and computation of comparative incidence rates may be misleading. A similar overlap was identifiable among schizophrenics and substance abusers in this sample who were not subsequently arrested (Zitrin, Note 4).

Overall, 202 or 23% of the patients studied were arrested one or more times during the 4-year period reviewed. Compared to the 45% arrest rate Sosowsky (Note 3) reported for his cohort of state hospital patients, this figure does not seem extreme, except for the fact that Sosowsky recorded arrests during an 8-year period surrounding hospitalization, whereas the Bellevue period of record surveillance was only 4 years.

Patient offenses were classified as violent

Table 5
Age-Adjusted Arrest Rates per 1,000 in 1972 for Violent Crimes

Offense	U.S. cities	Bellevue catchment area	Patient sample
Murder	.15	.45	.30
Aggravated assault	1.44	5.81	7.02
Robbery	1.06	8.81	8.38
Rape	.17	.57	1.15

Note. These data are from Zitrin, Hardesty, Burdock, and Drossman (1976).

crimes involving direct bodily harm (murder, assault, forcible rape, and sexual abuse), violent crimes involving potential for harm (robbery, burglary, weapons possession, possession of burglar's tools, arson, inciting to riot), and nonviolent crimes (presumably all misdemeanors except for simple assault, which is included with other forms of assault as a violent crime). The inclusion of *violent crimes involving potential for harm* in the violent crime category extends its meaning to somewhat less severe offenses than the term as used by others.

Using this classification, 85 or 10% of the 867 patients were arrested for violent crimes and 13.5% for nonviolent crimes. These 85 patients committed a total of 155 crimes of violence, the most common being assault, followed in order of frequency by burglary, weapons possession, and robbery. The age distribution of the violent offenders peaked in the 20–30-year interval, whereas the modal age of nonviolent offenders fell into the 30–40-year interval.

The 85 patients arrested for violent crimes during the 4 years under review were arrested a total of 366 times for various offenses—an average of 4 times each. Twenty-eight of them were arrested only during the 2 years before admission, 21 were arrested only after discharge, and 36 of this subgroup were arrested both before and after this hospital stay. Among the 117 patients arrested for nonviolent offenses, a larger proportion was arrested before the hospitalization than after the hospitalization (Zitrin, Note 4).

Zitrin and his colleagues analyzed crime categories in terms of the four diagnostic groups selected for study. Schizophrenics constituted about half of the sample and accounted for half of all arrests. Differences did emerge in relation to type of crime. Schizophrenics constituted two thirds of patients arrested for violent crimes involving bodily harm (21 out of 30), but were underrepresented among arrests for nonviolent offenses. These results agree with the findings of Giovannoni and Gurel (1967) that schizophrenic patients, when they behave disruptively, are indeed arrested and charged with criminal conduct rather than simply rehospitalized.

Both alcoholics and drug abusers were heavily overrepresented in all crime categories, as Brill and Malzberg (1962) observed earlier. Constituting only 7% and 6% of the patient sample, respectively, they accounted for nearly one third of all arrests. Addicts were more likely to be charged with violent crimes and alcoholics with misdemeanors. Like schizophrenics, patients diagnosed as neurotic were proportionately represented among total arrests and also within crime categories.

The final analysis reported was a comparison of patient arrest rates with those of residents in the same catchment area and with 1972 rates for cities nationally (Federal Bureau of Investigation, 1973), excluding children under age 15 from all groups. As Table 5 shows, arrest rates both for patients and for all residents of the Bellevue catchment area are far higher than those of pooled residents of all American cities. There is comparatively less difference between patients and their catchment area neighbors. The authors did not report the statistical significance of these differences, but it seems from inspection that across the four categories the difference is negligible, although for the offenses of rape and aggravated assault patient rates are higher. Since this catchment area group is most nearly comparable to the patient sample in terms of the social and demographic characteristics of all the studies reviewed, the diminished contrast observed here is noteworthy.

Zitrin et al. (1976) concluded that their data do not support the commonly held belief among mental health professionals that

the mentally ill commit fewer crimes than the general population. They urge provision of more effective aftercare services, together with the introduction of a provisional discharge category in which community stay is contingent on clinic attendance. In agreement with Brill and Malzberg, and Giovannoni and Gurel, they attribute the growing arrest rates among patients to "the increasing diversion of arrested persons from the criminal justice channels to mental hospitals" (p. 147).

A report of arrest rates among Wyoming state hospital patients provides a contrast of setting to the largely urban, industrialized areas previously investigated. Durbin, Pasewark, and Albers (1977) studied the arrest records of all patients aged 18 to 64 (286 men and 175 women) admitted to the only state facility in 1969, excluding patients remanded by criminal order for psychiatric evaluation. This sample was unusual diagnostically in that 63% of the male patients had a primary diagnosis of alcoholism and another 6% had such a secondary diagnosis. Arrest rates for male and female patients separately were derived from police records covering the 5 years before and the 5 years after hospitalization, from 1964 to 1973. Unlike investigators in any other study except that by Giovannoni and Gurel (1967), Durbin used a correction factor in computing arrest rates based on the mean number of days patients were hospitalized during this 10-year period.

Arrest rates of the patient sample were compared with those of the general Wyoming population aged 18 to 64, obtained from state records, for men and women separately. From both sets of rates, minor misdemeanors were excluded, including public intoxication, driving and traffic violations, gambling, vagrancy, and suspicion. In addition, rates were based on number of arrests, not on number of persons arrested. For both reasons, these rates are not directly comparable to those of other studies. Since only five female patients were arrested during the study period, analyses of results were based on males only.

Analysis of arrest by crime category is of doubtful reliability in view of the few cases in each of the 17 categories listed. Perhaps more meaningful is the pattern that emerges across categories: Patient arrest rates were higher in all categories of violent crime (crime against persons), four out of five types of crime against property, and drug offenses. They were lower for "white collar" crimes such as forgery, counterfeiting, and embezzlement.

The distribution of diagnoses among males in this Wyoming sample is uncommon (diagnoses of females were not given). Nearly 70% had a primary or secondary diagnosis of alcoholism, 14% were schizophrenic, 10% were personality disorders, and 3.5% were drug abusers. Surprisingly, in light of others' findings of an association between alcohol and crime, alcoholics were not overrepresented among arrested patients, nor were schizophrenics. Further, in this sample schizophrenics committed no violent crimes, in contrast to Zitrin et al.'s (1976) findings. The two groups with excessive arrest rates were patients with personality disorders and drug abusers.

Demographic variables associated with patient arrests included sex, age, marital status, and type of hospitalization. Single men aged 18 to 24 had a disproportionate share of arrests, as did those who were involuntarily hospitalized. Women constituted 38% of the patient group, but accounted for only 5% of the arrests.

Comparing arrest rates before and after hospitalization, two thirds of the arrests occurred before. Of the 49 men arrested during the 10-year period, 6 had no prior arrests and 35 had no subsequent arrests. In other words, the high recidivism noted elsewhere is not apparent here. Durbin et al. (1977) also noted a clustering of arrests in the year preceding hospitalization, suggesting that the disruptive behavior leading to the arrests may also have led to the decision to hospitalize. Here, as elsewhere, it is observed that hospitalization "may often serve as a diversionary adjunct to the criminal justice system" (p. 83).

The most recent investigation of arrest rates of discharged patients was conducted at the request of the New York State Commissioner of Mental Hygiene. Steadman, Melick, and Cocozza (Note 5) designed their study both to serve as a follow-up to Brill and Malz-

berg's (1962) 1947 study and to compare arrests of patients discharged in 1968 and 1975, before and after introduction of more liberal and rapid discharge policies in the state hospital system.

The 1968 sample consisted of every 14th patient aged 18 or more who was discharged from state facilities in that year, producing a study group of 1,920. In 1975, every 18th patient was selected, creating a sample of 1,938. In both samples, a small majority was male, 70% were white, 22% were black, and 7% were Puerto Rican. Most had not completed high school. Half in 1968 and 43% in 1975 lived in New York City. The most common diagnostic label was schizophrenia (27% in 1968 and 32% in 1975), followed by paranoid states (20% in both samples) and substance abuse (16% in 1968 and 19% in 1975). Over 80% of all the patients were released within 6 months of the current hospital admission. Nineteen percent of the 1968 sample and 26% of the 1975 sample had a history of prior arrests.

Lifetime histories of psychiatric hospitalization and criminal records before the current hospitalization were obtained from state agencies. The median follow-up period for both groups was 19 months (the briefest of any study reviewed). Patient arrest rates were compared with those of the general population of New York State over age 17.

Patients' total annual arrest rates were found to be more than double those of the general population in both years studied. In 1968 the patient rate per 1,000 was 73.5, compared to 27.5 for the general population. In 1975 the discrepancy was even greater: 98.5 for patients and 32.5 for the general population. Rates for both increased between occasions, but the patient rate accelerated more rapidly.

Analysis of arrests by crime category showed patient rates exceeding public rates within every category in both years with one exception: approximately equal rates for sex crimes in 1968. Greatest excess occurred in arrest rates for property, sex, and violent crimes in the 1975 sample and in arrest rates for drug, property, and violent crimes in the 1968 sample. During the 19 months after discharge, .9% of the 1968 sample and 1.7% of the 1975 sample committed violent crimes (homicides and assaults)—a small but increasing proportion.

The authors analyzed demographic, psychiatric, and historical factors associated with postdischarge arrests, first singly and then simultaneously. Taken one at a time, several variables were found to be significantly correlated with arrests, including youth, shorter hospital stays (presumably because the disorders were less serious or more transient), sex (fewer females arrested), ethnicity (in 1968 both blacks and Puerto Ricans had disproportionately high rates; in 1975 only blacks did), and admitting diagnosis. Personality disorders and substance abusers had the highest arrest rates. Although schizophrenics constituted about 25% of the sample in 1968 and 32% in 1975, only 3% and 6% were arrested in the respective years.

When multivariate analysis was applied to these data, diagnosis dropped out as a meaningful predictor; most of its relationship to arrest rates was accounted for by the variables of age and sex: Most personality disorders and substance abusers are young males. Using multiple regression analysis with the three variables with the highest zero order correlations to arrest rates—total prior arrests, age, and admitting diagnosis—Steadman et al. (Note 5) found that only the first two made independent contributions, together accounting for 13% of the variance in subsequent arrest behavior. Interaction effects were not analyzed as such.

In this study, as in virtually every other that looked at such data, a history of arrest before hospitalization turned out to be the best single predictor of postdischarge arrests so far identified. Here, as elsewhere, when arrest records of patients with and without prior arrests were separately analyzed and compared with those of the general population, postdischarge arrests of those with prior records substantially exceeded general population rates, whereas patients with no such history had lower rates than the general population in five out of the six crime categories studied (the exception was property crimes). Furthermore, Steadman and his

colleagues found a gradient such that patients with three or more prior arrests had more postdischarge arrests than those with two arrests, who in turn had more postdischarge arrests than those with one arrest. Not only was prior arrest itself a useful predictor but a pattern of similar offenses was also observed. Thus, the best predictor of subsequent arrest for violent crime was arrest for one or more violent crimes preceding hospitalization.

The predictive utility of a prior arrest history is widely recognized in the criminal justice literature. FBI studies (Federal Bureau of Investigation, 1973) of recidivism among over 200,000 persons arrested for federal offenses in the period 1970 through 1972 showed that 65% had been arrested at least twice, with an average of four arrests during the preceding 5 years. Furthermore, of these repeat offenders, 44% were rearrested in states other than that where first arrested. For the repeat offenders in 1972 alone, 55% of prior arrests took place in another state. Frequency of prior arrests was negatively associated with age; offenders under age 20 were arrested on the average every 3 months, whereas those over age 40 were arrested less than every 2 years. Parenthetically, such high interstate mobility among repeat offenders suggests the possibility of significant underenumeration of arrests among mental patients in those studies that relied only on single-state arrest data.

In Steadman et al.'s study, the total arrest rates for all patients combined are inflated by the presence of patients with criminal records. More such persons are found among the patient population of New York State mental hospitals than among the general population, and it seems to be this excess that accounts for higher total patient arrest rates. In addition, the proportion of patients admitted with arrest records has increased strikingly over time, from Brill and Malzberg's (1962) finding of 15% for male patients in 1947 to 32% of male patients in 1968 (Steadman et al., Note 5). By 1975, 4 out of 10 male patients had police records prior to their hospitalization. Approximately one third of the patients with arrest histories at each time period were arrested after discharge, compared to 2%–4% of patients without prior records who were subsequently arrested. As Steadman and his colleagues concluded, "Prior criminality rather than mental illness appears to be the primary explanation for the increasing arrest rates" (p. 16) observed.

Evaluation of the Evidence

Many questions about criminal behavior of mental patients have been raised and partially answered by the studies reviewed. It is, however, difficult to evaluate the evidence generated by each study when they are considered consecutively. In this section, therefore, I summarize relevant findings to clarify how much has been learned and what further information is needed.

Do Mental Patients Currently Have Higher Arrest Rates Than Members of the General Population?

Today and over the past 20 years, mental patients discharged from public facilities *as a group* have total arrest rates for all crimes that equal or exceed public rates with which they have been compared. Arrest and conviction rates for the subcategory of violent crimes were found to exceed general population rates in every study in which they were measured. The certainty of these findings must be tempered by consideration of design limitations including nonequivalent comparison groups and lack of attention to variables such as age and social class.

Have These Rates Changed Over Time?

The arrest rates of paroled and discharged patients based on pre-1950 records consistently were found to be lower than those reported for the general population. There has been a pronounced relative as well as absolute increase in arrests of mental patients since then; that is, whereas arrest rates for both patients and the general public have increased, the rate of acceleration for patients has been much greater.

What Factors Have Contributed to This Upward Trend in Arrest Rates?

At least two developments may account for the observed changes, both of which are fundamentally related to the evolving social role of the mental hospital in our society. First, there is the change in hospital policies regarding involuntary admission and retention of patients and the likelihood and timing of their discharge. In the past, there were comparatively few limitations regarding grounds for involuntary civil commitment. In contrast, recent legal reforms have largely restricted such commitment to situations in which the prospective patient is perceived as potentially dangerous to himself or others (Cocozza & Steadman, Note 2). Although psychiatric predictions of dangerousness are admittedly inaccurate (Steadman, 1973; Stone, 1975), it does seem probable that these restricted criteria alter the nature of the patient population and enhance the probability that discharged patients may be at greater risk for subsequent dangerous behavior.

Duration of commitment and discharge policies have also changed. Forty years ago, patients were often committed for decades or for life in large state facilities, physically removed from their communities of origin. As Pollock (1938) described in detail, patients who were released had to meet a series of requirements, not only with respect to their psychiatric status and social functioning but also regarding available familial resources. Once these recovered, socially acceptable, and cooperative patients with welcoming and protective friends and relatives were paroled, their progress was monitored by an elaborate, extensive, and compulsory system of home and clinic visits. If parole authorities were notified of a change in status, the patient could be rehospitalized at once. Although New York State's hospital system may have been more cautious about discharges than others (Giovannoni & Gurel, 1967), this general system prevailed nationally.

Today in New York State facilities as elsewhere, the average patient stay is 30 days. In acute-care units, patients are usually discharged within 2 weeks. Nationally since the 1950s hospital stays have become progressively shorter, and hospital populations have declined although admissions have not, leading to many more discharged patients in the community. Since the late 1960s heavy emphasis has been placed on community-based treatment on a voluntary basis. As soon as the acute symptoms of hospitalized patients subside, usually with the help of psychotropic medication, patients are discharged. There is no compulsory aftercare or follow-up. In short, virtually all patients admitted in the past several years are promptly returned to the community. The state mental hospital's traditional role as a "warehouse for the unwanted" has been transformed into a brief way station for the most acutely disturbed.

The second major change concerns a shift in the way the civil machinery distributes disruptive members of the community. In the past, a large majority of offenders were sent to jail regardless of their mental status. Since World War II it has become increasingly common for offenders who appear to be mentally disturbed or who have a history of psychiatric hospitalization to be dispatched to the mental health rather than to the criminal justice system. This phenomenon seems related to the fact that, in most jurisdictions, the criminal justice system is inundated with far more defendants than can be handled. Such overcrowding evidently has encouraged the use of psychiatric hospitalization as an alternative method of removing disturbing people from the community. Consequently, an increasing number of mental patients have police records. It is reasonable to expect for this reason alone that, as all patients are promptly discharged, mental patients returning to the community will, as a group, have a higher arrest rate than in the past when the patient population had a different composition. As Giovannoni and Gurel (1967) have stated the point, "It is primarily in the way mental hospitals are utilized by the community, and particularly as this influences the kinds of patients admitted and the number and kinds of patients released, that one is likely to find the major sources of variation in ex-patient crime rate" (p. 151).

What Are the Best Predictors of Postdischarge Arrests?

It has been repeatedly and convincingly demonstrated that the small subset of patients who have prior criminal records accounts for a large majority of postdischarge arrests. This is the single best predictor so far identified. Other predictors, which are significantly associated with postdischarge arrests but not large in their effect, include male sex, youth, and unmarried status. Short hospital stay and diagnoses of alcoholism, drug abuse, and personality disorder are also associated with arrest risk when analyzed separately, but their predictive value seems to be largely accounted for by their relationship to sex and age, as Steadman et al. (Note 5) demonstrated in their multivariate analyses. Despite the consistency with which these predictors have been identified, their effect size is evidently small. Much remains to be learned in the prediction of disruptive, illegal behavior by mental patients after their return to the community.

What is the Association Between Arrest Risk and Diagnostic Category?

It is generally believed that patients diagnosed as personality disorders, alcoholics, and drug abusers are the most likely to display antisocial and aggressive behavior. There is less consensus about whether these three diagnostic labels describe mental illness. In some epidemiological studies of true prevalence rates, investigators systematically exclude these categories (e.g., Gove & Tudor, 1973) and focus exclusively on neuroses and functional and organic psychoses. In addition, states vary in their policies of admitting patients with a primary diagnosis of alcoholism more than once to state facilities, so that their proportion of the total patient population varies by area as a function of administrative policy.

In those studies that generated interpretable findings about crime rates of different diagnostic groups in relation to their size in the patient sample under study, alcoholics, addicts, and personality disorders were in each case found to have excess rates (Brill & Malzberg, 1962; Durbin et al., 1977; Zitrin et al., 1976; Steadman et al., Note 5). The consistency of these results lends them credibility. The effects of age and sex must be considered, however, in view of Steadman et al.'s observations regarding their associations. Because two of the four studies dealing with diagnostic differences were based on male samples only (Brill & Malzberg, 1962; Durbin et al., 1977), sex is evidently not a critical factor. The role of age remains unclear. Giovannoni and Gurel (1967) found, in their group of older, chronic schizophrenic males, that nearly three quarters of those arrested had drinking problems. More direct evidence would be available by studying differential diagnostic roles in an age-stratified sample to see if the differences prevail at various ages. At present, one may conclude that patients with diagnoses of personality disorders, alcoholism, and drug dependency have disproportionate arrest rates. Whether this is caused by the nature of their disorders or by demographic characteristics associated with their distribution in the general population remains unclear.

Evidence is less consistent regarding the subsequent criminal activity of patients diagnosed as schizophrenic. In those studies in which schizophrenics constituted half or less of the patient sample, their arrest rates were not disproportionately high. In the most detailed analysis of arrests by diagnostic group, conducted by Zitrin et al., schizophrenics were found overrepresented among those patients who committed violent crimes with bodily harm but not overrepresented in terms of overall arrest rates for all crime categories combined. In two samples in which all or most of the patients were schizophrenic (Giovannoni & Gurel, 1967; Sosowsky, Note 3, San Mateo sample), arrest rates were much higher for patients than for control populations, especially for violent crimes; that is, schizophrenic samples had the same excess of crimes, compared to control groups, that characterized samples with predominantly nonschizophrenic patients. From the preliminary evidence available, it seems that arrest rates of schizophrenics do not exceed those of other diagnostic groups, with the possible exception of arrests for violent crimes (homi-

cides and assaults) in which their rates may be higher. Critical and uncontrolled are the factors of age and social class, which require evaluation before firmer conclusions can be derived.

Are Mental Patients More Likely To Be Arrested for Certain Types of Crime?

Traditionally, it was believed that mental patients, when arrested at all, were charged with minor offenses such as loitering, vagrancy, or public intoxication. It was an unpleasant surprise to learn not only that patient arrest rates were the same or greater than those of the general population in recent years but that this excess was particularly pronounced in the category of felonies, and specifically, of violent crimes or crimes against persons. Six investigators, using eight patient samples, found higher arrest (and/or conviction) rates for the crimes of homicide and assault among patients than among control groups (see Table 2). The magnitude of this excess ranged from 1½ to 29 times greater than general population rates. No studies reported contrary findings. The consistency and size of the differences across patient samples that vary in time, place, and diagnostic composition make the differences convincing. It seems reasonable to conclude that mental patients are more likely to be arrested for assaultive and sometimes lethal behavior than are other people.

No clear pattern emerges regarding the relative frequency with which other crimes are charged against mental patients. Rappeport and Lassen (1965, 1966) found the highest arrest rates for robbery by males and for aggravated assault by females. Giovannoni and Gurel (1967) reported that after violent crimes, which accounted for 27% of police contacts among their patients, the next most common offenses were drunkenness (23%), motor vehicle thefts (13%), and crimes against property (12%). Durbin et al. (1977) reported a high incidence of drug offenses among their predominantly alcoholic patients, and Steadman et al. (Note 5) found the most common offenses in their 1968 sample to be drug, property, and violent crimes; the most common offenses in their 1975 sample were property, sex, and violent crimes. In short, apart from assaultive behavior, mental patients are apparently no more likely to be arrested for some crimes than others, judging from the limited evidence at hand.

Does Hospitalization Reduce the Probability of Recidivism Among Patients With Prior Arrest Records?

This question is interesting because a positive finding would provide support for the notion of a causal association between mental status and crime, in contrast to the opinion of several investigators that disturbed and criminal behaviors may coexist but are causally independent. No definite answers can be generated by analysis of recidivism rates among patients in the absence of data regarding recidivism among nonhospitalized offenders. The only authors who tried to assess the latter were Brill and Malzberg (1962), but they did not have access to reliable recidivism data for the general criminal population.

Despite the absence of control data, several authors have discussed the issue of recidivism rates among patients. Cohen and Freeman (1945) were the first to suggest that hospitalization may reduce recidivism, based on their finding that only 26% of patients arrested before being hospitalized were also arrested after discharge. The only others to be impressed with a decline in arrests after hospitalization among patients with records were Durbin and his colleagues (1977). Of the 43 men in their sample who were arrested in the 5 years before hospitalization, only 8, or 19%, were also arrested within 5 years after discharge. They concluded that "factors associated with hospitalization . . . may have influenced the reduction in arrest rates after hospitalization" (p. 83).

Other investigators who discussed recidivism disagreed. Rappeport and Lassen (1965) stated, "As best we can interpret our data, there was a tendency toward recidivism not unlike that seen in the general community." Brill and Malzberg (1962) and Steadman et al. (Note 5) interpreted their findings similarly. Zitrin et al. (1976) only reported

Table 6
Postdischarge Arrest Rates of Mental Patients With and Without Prior Arrest Records

Authors	Years of discharge	No. of patients with prior records	Follow-up period	Percentage arrested with prior records	Percentage arrested without prior records
Cohen & Freeman (1945)	1940 to 1944	314 (18% of sample)	$M = 2$ years	26%	<1%
Brill & Malzberg (1962)	1947	803 males	5½ years	34%	2%
Zitrin, Hardesty, Burcock, & Drossman 1976)	1969 to 1971	64 (only those arrested for violent crimes)	2 years	56%	—
Steadman, Melick, & Cocozza (Note 5)	1968	343 males	19 months	31%	2%
Steadman, Melick, & Cocozza (Note 5)	1975	435 males	19 months	29%	4%
Durbin, Pasewark, & Albers (1977)	1969	43	5 years	19%	3%

recidivism rates for the 85 patients in their sample arrested for crimes of violence for 2 years before or after the hospitalization under study. One third were arrested only before, one quarter only after, and 42% both before and after their hospital stay, producing a total recidivism rate of 56% among patients who committed one or more crimes of violence. This rate is the highest of any reported, as seen in Table 6.

In summary, reported recidivism rates for arrests among discharged mental patients range from 19% to 56%. These rates were derived from different periods of record surveillance, include different crime categories, and were gathered over a period of 30 years. In contrast, only 2%–4% of patients without prior arrest records were arrested within 5 years after discharge. This analysis of recidivism rates reinforces the conclusion noted earlier that a history of prior arrests is a useful predictor of arrest risk after discharge. Without equivalent recidivism rates for the nonhospitalized criminal population, no conclusions are warranted regarding the impact of hospitalization on the risk of future antisocial behavior.

Conclusions

From the information presently available, it seems that discharged mental patients as a group are not significantly less likely than others to exhibit dangerous or illegal behavior. At the present time there is no evidence that their mental status as such raises their arrest risk; rather, antisocial behavior and mentally ill behavior apparently coexist, particularly among young, unmarried, unskilled, poor males, especially those belonging to ethnic minorities. It is unlikely that most people would care to have such neighbors even in the absence of a history of psychiatric hospitalization.

The major factor associated with increases in arrest rates of discharged mental patients in recent years is the increased proportion of mental patients who have arrest histories before their hospitalization. For males in New York State, for example, this proportion

has risen from 15% to 40% in the past 30 years. This change of hospital clientele seems to represent an alteration in application of the civic machinery according to which the mental health system is being increasingly used as an adjunct to the criminal justice system.

Arrests are fairly infrequent events even when mental patients are inappropriately considered as a single group. In the 18 months after discharge from New York State hospitals in 1975, for example, 90% of patients were not arrested. When patients with arrest histories, primary diagnoses of substance abuse, and personality disorders are considered separately, the remainder of the patient group appears to be considerably less dangerous than are those members of the general public who are not mentally ill.

It is recommended that future studies emphasize selection of equivalent comparison groups, integration of patient data with arrest and recidivism rates of the nonhospitalized population, greater consideration of geographic issues, and improved data analysis. The majority of both mental patients in public institutions and criminals come from similar population subgroups. Both have disproportionate numbers of poor, unskilled, uneducated, unmarried young men, many of whom belong to low-status ethnic groups. If arrest rates of mental patients were compared to those of their nonhospitalized peers using these criteria, it is quite possible that the observed excess of arrests of discharged mental patients would no longer be apparent. This does not detract from the validity of the conclusion that as a group mental patients are more likely to be arrested, especially for crimes of violence, than is the total population, the majority of whom are obviously not poor, unmarried males that belong to ethnic minorities.

Based on the limited evidence available, I conclude that patients discharged from mental hospitals are not, by virtue of their psychiatric disorders or hospitalization experience, more prone to engage in criminal activity than are people demographically similar to them who do not have a history of mental illness. Although patients considered as a group do have higher arrest rates than nonpatients considered as a group, it is largely because the patients include in their midst a disproportionate share of people with prior police records. The most immediately obvious method of reducing criminal activity among discharged mental patients is to reexamine and modify current procedures that contribute inappropriately to the use of mental hospitals as alternatives to the criminal justice system.

Call for Nominations

The APA Publications and Communications Board invites nominations for the editorship of *Psychological Bulletin* for the years 1981 through 1986. R. J. Herrnstein is the incumbent editor. The new editorial appointment will be made this year in order to provide continuity in publication of the journal. The editor-elect will start to receive manuscripts in 1980 to prepare for issues published in 1981, the first year of the new editorial term.

To nominate candidates, prepare a brief statement of one page or less in support of each nomination. Submit nominations no later than April 1, 1979, to Anita DeVivo, P&C Board Liaison, APA, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

Comment on Banks's "White Preference in Blacks: A Paradigm in Search of a Phenomenon"

John E. Williams
Wake Forest University

J. Kenneth Morland
Randolph-Macon Woman's College

Banks concluded from the studies he reviewed that the evaluative preference and self-identification responses of Afro-American children toward stimulus alternatives representing light- and dark-skinned persons conformed to simple chance rather than indicating a "white preference in blacks." This interpretation is challenged as misleading because of Banks's dismissal of the importance of comparisons by race in the literature cited and because of his failure to cite a number of relevant studies of race and color bias, the results of which are inconsistent with his conclusion.

In a recent *Psychological Bulletin* article, Banks (1976) reviewed a number of studies in which young Afro-American [1] children had made preference and self-identification responses to light- and dark-skinned persons, as represented by dolls, puppets, line drawings, and photographs. Banks concluded that the findings of these studies, viewed in toto, could be attributed to chance and, hence, provided no systematic evidence of a bias favoring light-skinned persons among Afro-American children. Having been active in this area of research, we feel that Banks's conclusion is misleading and requires a reply. We are concerned primarily with two matters: first, Banks's abrupt dismissal of the relevance of comparing the responses of Afro-American children to those of Euro-American children and other groups, with a consequent distortion of the significance of much of the research cited; second, Banks's omission of the findings of additional relevant studies that are in conflict with his conclusion, particularly recent and more methodologically sophisticated studies of preschool children's attitudes toward race and color.

We begin by acknowledging that Banks was correct in pointing out that in most of the studies he cited the racial preference and self-identification responses of Afro-American children can be attributed statistically to chance. This was the case even when a majority of the Afro-American children gave "white-preference" responses, as for example in the picture–interview studies cited in which more than half of preschool Afro-American respondents indicated that they would prefer to play with the Euro- rather than with the Afro-American models, that they looked more like the Euro- than the Afro-American models, and that their mothers looked more like the Euro- than the Afro-American models (Morland, 1962, 1963). This was also true for another study Banks cited in which preschool Afro-Americans who had demonstrated they could use racial classification terms [2] correctly were asked to which race they themselves belonged: 52% responded correctly, 16% did not know or refused to say, and 32% responded incorrectly (Morland, 1958). In other words, half of the Afro-American

[1] We prefer to use the terms *Afro-American* and *Euro-American* rather than *black* and *white* to designate these racial categories for reasons we have explained elsewhere (Williams & Morland, 1976, pp. x–xi).

[2] In such studies, the racial classification terms best known to the children are checked empirically at the time of each testing. The racial designation of Euro-Americans as *white* has not changed; however, racial designations of Afro-Americans have changed. In the 1958 study it was *colored;* later it shifted to *Negro;* now it is *black*.

children made correct self-classification by race, and half did not. Subsequent studies of preschool Afro-American children have yielded similar results (Morland, 1963, p. 239; 1969, p. 368; Savory, Note 1).

One might assume from such apparently inconsistent responses that racial self-classification is unimportant in American society and/or that preschool American children are not old enough to recognize and attach significance to racial differences. There is considerable evidence, however, to show that racial classification has been and continues to be important in American society, and, further, the assumption can be supported that a societal norm exists that calls for Americans to identify with and be proud of the race to which society says they belong (Williams & Morland, 1976, pp. 3–32, 251). Are preschool American children old enough to have learned to recognize racial differences and to know their own racial classification? It is at this point that the comparison by race becomes important. In the Morland studies referred to above, Euro-American preschoolers did not respond randomly; rather, they chose the Euro- over the Afro-American models in every response at statistically significant levels, according to the criterion percentages employed by Banks (1976, Table 1, p. 1180). The Euro-American preschoolers chose the Euro- rather than the Afro-American models as the ones they preferred to play with, the ones they looked more like, the ones they would rather be, and the ones their mothers looked more like; and of those who had demonstrated that they knew how to use racial classification terms, 99.5% said they were "white" (Morland, 1958, 1962, 1963). It is clear from these findings that preschool American children can learn to recognize race differences and make correct racial self-classification.

While Banks (1976) realized that differences in response by race had been found, he appears to have dismissed the relevance of comparisons by race because of his disagreement with what he saw as their implicit rationale, namely that "same-race choices of white subjects may be believed to represent an a priori standard of rational behavior" or "a standard of mental health" (p. 1180). There is, of course, a more general rationale for making these comparisons by race. It is the desire to increase understanding of the development of racial preference and identity by seeing if they are significantly related to the race of the respondent. The same rationale applies to comparisons by age, sex, socioeconomic status, and region, which are found in the studies Banks cites. If it is granted that racial classification is important in American society, that a societal norm for own-race identification exists, and that preschool American children are old enough to recognize and attach significance to racial differences, the question arises from the studies Banks reviewed as to what else there is about American society and the nature of racial bias that leads to such different responses in young American children by race. Banks avoided dealing with this question, which we believe deserves serious pursuit. We have done this by comparing racial identity and attitude responses of children in other societies, noting how social structure, norms, and reactions to color are related to racial self-identity and attitudes (Morland, 1969; Morland & Williams, 1969; Williams, Morland, & Underwood, 1970; Morland, Note 2). From these and other studies, we have constructed what we hope will be a useful theoretical model for increasing understanding of the development of race bias in young children (Williams & Morland, 1976, pp. 280–283).

Related to Banks's (1976) dismissal of comparison by race is the inaccuracy that comes in citing the 1958 and 1963 studies by Morland to support his assertion: "Reliance upon white comparative frames has largely perpetuated the notion of black self-rejection . . ." (p. 1185). In neither of these studies was any mention made of racial self-rejection, and it is indeed strange that Banks failed at this point to bring in the 1962 study by Morland, which Banks used in other places in his article. That study explicitly stated as one of its conclusions: "Preference for one race did not imply rejection of the other" (Morland, 1962, p. 279). This conclusion was based on the racial acceptance measure in which no choice was involved. Both the Afro- and Euro-

American respondents readily accepted models of both races, and rejection based on race was exceedingly rare. This absence of racial self-rejection has also been explicitly pointed out in other studies by Morland (1966, p. 26; 1969, pp. 364–366; Note 3, pp. 5–6; Note 4, p. 6) and in the review by Williams and Morland (1976, pp. 191–192).

In analyzing the studies he reviewed, Banks did not make a distinction between responses of preschool and in-school Afro-Americans. We have discovered that unless this is done, the conclusions can be misleading. In our analysis of a number of studies, including several of those cited by Banks, we found that in-school Afro-American children were significantly more likely than preschool Afro-Americans to prefer and identify with Afro-American models (Williams & Morland, 1976, pp. 176–201). For example, less than 2% of in-school Afro-American children of high racial classification ability gave incorrect racial self-classification responses. This was in marked contrast to the preschool Afro-Americans of high racial classification ability of whom as many as 30% gave incorrect racial self-classification responses. This difference between preschool and in-school Afro-American children questions Banks's (1976) contention that the high level of own-race preference and identification by Euro-American children could be an expression of their "ethnocentrism" (pp. 1180, 1185). By the time Afro-American children enter public school, they evidently respond in a similar way to Euro-American children in own-race preference and identification. Rather than being "ethnocentric," these responses can be accounted for as a recognition by the children of the racial category to which American society says they belong and as an expression of the American norm that persons should be proud of and accept their racial affiliation.

Banks's (1976) paper was submitted in 1975 and the studies he reviewed appear to cover the years from 1939 through 1973 (Table 3, p. 1184). We have already cited several studies of that period that were not referred to, for example, those by Morland in 1966 and 1969. Banks also omitted a number of research studies of racial attitudes in Afro-American children published during 1973–1975, studies that used different techniques from those he cited: Best, Smith, Graves, and Williams, 1975; Mabe and Williams, 1975; Spencer and Horowitz, 1973; Williams, Best, and Boswell, 1975; Williams, Best, Boswell, Mattson, and Graves, 1975; and Williams, Williams, and Beck, 1973. Also neglected were several doctoral dissertations and master's theses: Baugher, 1973; H. P. McAdoo, 1970; J. L. McAdoo, 1970; Skinto, 1969; Vocke, 1971; Walker, 1971; Whiteside, 1975. We have reviewed the findings from the foregoing studies elsewhere (Williams & Morland, 1976). Without exception, these studies have provided evidence of a tendency for young Afro-American children to evaluate representations of light-skinned persons more favorably than those of dark-skinned persons.

Three of these studies will be noted for illustrative purposes. H. P. McAdoo (1970) administered the 12-item racial attitude procedure devised by Williams and Roberson (1967) to preschool Afro-American children in Michigan and Mississippi. It was found that the mean scores in both groups departed significantly from chance in the direction of pro-light-skin bias. A second study was conducted by Spencer and Horowitz (1973), who studied the modification of color and race bias among Afro- and Euro-American preschoolers in Kansas. Although the modification procedures were found to be generally effective, the authors reported that both Afro- and Euro-American children in the nontreated control group displayed a bias for light-skinned persons throughout the study. A third study is that by Williams, Best, Boswell, Mattson, and Graves (1975), who described the development and standardization of the Preschool Racial Attitude Measure II (PRAM II). In this 24-item picture–story procedure, the child selects between drawings of light- and dark-skinned persons as the one described in an accompanying story that contains 1 of 24 evaluative adjectives. The PRAM II scores have a 24-point range and, thus, provide a more sensitive measure of attitude than the "one-item tests" reviewed by Banks (1976, Table 2, p. 1182). When PRAM II was administered to Afro-American preschoolers in North Carolina, the mean scores were found to depart significantly from chance in the direction of pro-light-skin bias but not to as ex-

treme a degree as among Euro-American children of comparable age.

Additional light has been thrown on the development of race bias in children through research on racial attitudes in other societies. As illustrations, we note the recent studies employing the PRAM II procedure with preschool children in France, Italy, Germany, and Japan, who have had little direct contact with dark-skinned persons or with concepts of race associated with color (Best, Field, & Williams, 1976; Best, Naylor, & Williams, 1975; Iwawaki, Sonoo, Williams, & Best, 1978). The findings from these studies indicated that these foreign children also displayed pro-light-skin bias, which suggests to us that contact with racial concepts of the type encountered in the United States is not necessary for the development of such bias.

Banks (1976) stated in the abstract of his article that his concern was with the "choice behavior among blacks toward white and black stimulus alternatives" (p. 1179). In view of this, it is surprising that he made no reference to studies of the evaluative responses of Afro-American children to the colors black and white (Skinto, 1969; Stabler, Johnson, Berke, & Baker, 1969; Stabler, Johnson, & Jordan, 1971; Vocke, 1971; Williams, Boswell, & Best, 1975; Williams & Rousseau, 1971). As an illustration of the findings from these studies, Williams and Rousseau (1971) administered a 12-item picture–story procedure to Afro-American preschoolers who were asked to choose between a white or a black animal as the one described in the associated story. It was found that the children displayed a significant tendency toward the association of positive evaluative adjectives with the color white and negative evaluative adjectives with the color black. Similar findings were reported by Williams, Boswell, and Best (1975), although the degree of prowhite bias among Afro-American children was not as extreme as that found among Euro-American children of comparable age. We think it is instructive also to note that a similar prowhite bias has been documented among preschool-aged children in a number of other countries including England, Scotland, France, Germany, Italy, and Japan (Best, Field, & Williams, 1976; Best, Naylor, & Williams, 1975; Dent, 1976; Iwawaki, Sonoo, Williams, & Best, 1978). These findings appear to parallel the findings from studies with young adults, which point to a pan-cultural tendency to evaluate white more positively than black (Adams & Osgood, 1973; Williams, Morland, & Underwood, 1970).

We agree with Banks that none of these findings should be interpreted as evidence of "racial self-rejection" by Afro-American children, a view that is supported by the research findings on race and self-esteem that have failed to indicate any consistent differences between Afro- and Euro-American children. Our theory, which is elaborated elsewhere (Williams & Morland, 1976), is that when pro-light-skin bias and pro-white-color bias are encountered in preschool children these phenomena can be viewed, most parsimoniously, as reflections of a general prolight/antidark bias. We propose that this bias originates in most young humans as a result of early learning experiences (e.g., with the light of day and dark of night) and is subsequently reinforced through social processes, occurring in almost all cultures, in which light is used to symbolize "goodness" and dark to symbolize "badness."

By way of summary, we feel that Banks's refusal to deal with comparisons by race in the studies he reviewed and his failure to consider the findings from other more methodologically sophisticated studies of attitudes toward race and color have led him to an over-simplified and misleading conclusion. Pro-light-skin bias among preschool Afro-Americans is not a particularly powerful phenomenon. It exists, however, and needs to be recognized by all persons who are concerned with the development of young children in our multiracial American society.

On the Importance of White Preference and the Comparative Difference of Blacks and Others: Reply to Williams and Morland

W. Curtis Banks
Social Learning Laboratory, Educational Testing Service
Princeton, New Jersey

Gregory V. McQuater and Jenise A. Ross
Princeton University

It has been contended that, in contrast to the argument set forth by Banks (1976), the phenomenon of white preference does obtain among blacks, albeit minimally, and further that such a phenomenon is important in its relationship to and implications for the social adaptation of such persons. The present paper argues, however, that even within those examples set forth of the significant demonstration of white preference in blacks, insufficient evidence is presented to reject the null hypothesis of nonpreference. It is further considered whether empirical evidence supports the validity of such a phenomenon as a measure of self-concept or social behavior preferences and whether therefore the "importance" of white preference as it obtains in blacks, or differentiates blacks from whites, can be sustained.

White preference among blacks is, as stated by Williams and Morland (1979), "not a particularly powerful phenomenon" (p. 31). A serious question is whether it is a phenomenon at all (see Banks, 1976), although it must be conceded that it can be expected, as much as any other event of behavior, at least to occur in some of the people some of the time. In this regard, Williams and Morland (1979) have presented certain evidence omitted from an earlier discussion by Banks, which they argue provides support both for the existence and the importance of the phenomenon of white preference in blacks. However, we should consider this evidence in light of the accepted criteria by which we separate those things that exist some of the time from those that have reliable and predictable occurrence in the behavior of a specifiable population and those things that are felt to be important from those that have a demonstrable validity. Even if it were considered for the moment that such a phenomenon does exist, the question of its meaning and importance would remain. Since in the analysis of importance, the question of existence must inevitably be raised, we focus here primarily upon the question of importance with respect to the three specific examples of that evidence cited by Williams and Morland (McAdoo, 1970; Spencer & Horowitz, 1973; Williams, Best, Boswell, Mattson, & Graves, 1975) as supportive of both the existence and the importance of white preference in blacks. For this purpose we might take, for example, the framework suggested by Cronbach and Meehl (1955) in which there are three levels at which we may ask the question of whether white preference, as measured within the common paradigms, is a valid phenomenon among blacks.[1]

The authors thank J. Rudy for his helpful comments on an earlier draft of this paper.

Requests for reprints should be sent to W. Curtis Banks, Social Learning Laboratory, Educational Testing Service, Princeton, New Jersey 08541.

[1] *Webster's New Collegiate Dictionary* (1974) defines the word "important" as pertaining to something that is "valuable in content or relationship," which is close to the concept of validity as it applies to the content or criterion significance of psychological measures.

Content Validity

The content validity of a measure of white preference would rely upon the specification of a universe of content that is accepted as defining the phenomenon and the demonstration that the measure constitutes a sample of that universe. Such measures as those in which subjects are asked to express choices of dolls, puppets, and hypothetical other children may, in this sense, derive their validity solely from the fact that they sample responses directly representative of those to which they wish to generalize in the real world. However, the overall content validity of such measures as indicative of white preference in blacks would rest upon both the representativeness of the stimulus items themselves and the ability of such items to evoke white-preference choices. One instrument whose ability in this regard has already been asserted is described by Williams, Best, Boswell, Mattson, and Graves (1975).

In their procedure, subjects are asked to make preferential selections between white- and black-representative stimuli.

Williams et al. (1975) reported a binomial test of probability for the within-subjects frequencies of white-stimulus choices across the 24 replicated items of their Preschool Racial Attitude Measure II (PRAM) instrument. Moreover, they reported that 60% of white subjects selected the white-representative stimuli more often than would be expected by chance across the 24 within-subjects replications, as did 39% of black children. However, their contention of the significance of the choice behavior of 39% of blacks who chose the white stimuli on 17 or more of the items, while intuitively compelling, is statistically inappropriate, due to the nonindependence (within-subjects derivation) of those frequency observations. While this within-subjects replication of preference choices may yield a more reliable categorization of respondents into white-preference and other classifications than did the various one-response procedures of past research, it is these between-subjects category frequencies that are appropriately testable by binomial and related analyses. In this regard, fully 72% of white children chose the white stimuli at (within-subjects) rates that led Williams et al. (1975) to label them as indicating "definite" or "probable" bias. While 52% of black subjects fell within these two categories, fully 58% could have been expected to do so by chance alone.

Williams and Morland have also referred to the "significant" white-preference frequencies reported by Spencer and Horowitz (1973). The choices of the control-group blacks to which Williams and Morland refer as having displayed white preference were reported only in terms of the mean percentage of white choices (approximately 70%). Within a sample of eight, this magnitude of frequencies across subjects would not reject the null hypothesis, since a percentage of roughly 85 would be required at the .05 level. However, since the data were reported as mean percent of choices within subjects, we might instead attempt to assess its significance by a t-test comparison against 50%. Using the error term from the analysis of variance reported by Spencer and Horowitz (1973), this test would yield a t value of approximately 1.31, hardly approaching significance even at the .05 level. Consequently, the phenomenon of white preference in blacks fails to obtain in this example as well. In fact, the instrument devised by Williams et al. (1975) may contain stimulus items fully representative of the domain to which we may wish to generalize, but the evidence derived from its application provides empirical support for a content-valid measure of nonpreference in blacks, quite contrary to the assertion of Williams and Morland.

Criterion Validity

At another level, however, it may be argued that such a strict reliance upon the measured phenomenon as inherently content valid simply regresses to the analysis and arguments already set forth by Banks (1976) and currently under criticism. Rather, within the framework of criterion validity, the phenomenon of white preference as measured within these paradigms may derive its importance from the fact that it concurs with racial self-concepts (as a concurrent criterion) or that it predicts natural events of racial selection

and preference among black children in a real-world domain outside the laboratory (as a predictive criterion).

Empirically, it can be said to do neither. For example, in the study by McAdoo (1970) to which Williams and Morland have referred, black children from the North and the South were measured concurrently for self-concepts and for racial preferences. In this instance, the Williams et al. (1975) PRAM measure of racial preference, in fact, was found to be unrelated to northern black children's self-concepts. And contrary to the assumptions of concurrent-criterion validity that might derive from that instrument, measured white preference among southern black youngsters was directly related not to negative self-concepts but to positive self-concepts.

This is not an isolated example of the lack of criterion validity of preference measures for blacks. Porter (1971) investigated the racial preferences of black and white children and the patterns of their play and friendship preferences in the natural social setting of school. Although children from both samples were found to indicate racially influenced biases in their choice behavior within the laboratory procedure (similar to that used by Williams et al., 1975), Porter reported that "race seemed to play little part in determining the [predictive criterion of actual] friendship patterns" (p. 167).

Construct Validity

It might be argued in response to the points discussed above that the phenomenon of white preference in blacks lacks sufficient conceptual specificity to permit a test of its importance or meaning by so precise a set of content- or criterion-validation hypotheses. We would concur. Were it assumed rather that such measured phenomena represent some underlying hypothetical construct of personality, it would remain to be demonstrated that such an inferred construct has validity. The validation of white preference in blacks as representing the construct, for instance, of negative self-concept could proceed via systematic observations of positive correlations between it and logically convergent behavioral phenomena and negative correlations between its occurrence and that of logically divergent phenomena among blacks. In this regard, one might expect that blacks would with reasonable consistency express a conception of their own qualities and abilities for successful functioning as lower than those of white persons; one might expect, as well, to find that success in such domains as school would relate profoundly to such racially influenced self-assessments among blacks. Certain empirical evidence stands in opposition to both the former (see, e.g., Wylie, 1963; Wylie & Hutchins, 1967) and the latter (Coleman, Campbell, Hobson, McPartland, Mood, Weinfield, & York, 1966; Guggenheim, 1969; Hunt & Hardt, 1969; Wolkon, 1971) notion. Similarly, within a population whose qualities of racial identification and valuation are supposed to work so destructively against a sense of personal optimism and worth, one would hardly expect aspirations toward intellectual/academic excellence and occupational/socioeconomic ascendance to obtain. Yet they do and most often in measure equal to or beyond that of persons whose sense of racial identity ought to place them in a relatively superior position. (See Boyd, 1952; Brook, 1974; Ducette & Wolk, 1973; Gist & Bennett, 1963; Phillips, 1972.)

In summary, scant evidence exists of the tendency of blacks to express preferential evaluative orientations toward white characteristics. Furthermore, the validity of such a phenomenon as a measurement of content or predictive significance for white preference within the real world of social choices, self-esteem, or racial pride seems equally unsupported by empirical evidence; even (or, perhaps, especially) in the case of those examples of research cited by Williams and Morland. Why should we retain for the analysis of behavior in blacks either (a) a conceptual/methodological paradigm in which the null hypothesis pertaining to an empirical phenomenon fails consistently to be rejected or (b) a sense of the importance of a phenomenon whose meaning fails to be verified within any of the existing validation paradigms? Neither the evidence reviewed earlier by Banks (1976) nor that specifically cited by Williams and Morland suggests that we should.

Using Quasi *F* to Prevent Alpha Inflation Due to Stimulus Variation

John L. Santa, John J. Miller, and Marilyn L. Shaw
Rutgers—The State University

The nominal alpha level may be very inflated in much of the published literature where the conventional *F* test is used. This alpha inflation is often caused by ignoring stimulus variation or treating it as a fixed effect. The present article illustrates this problem in a variety of areas and discusses the use of Quasi *F* ratios as a means of achieving generality over both subjects and stimuli. Monte Carlo experiments are reported that examine the performance of the Quasi *F* in a variety of realistic situations in which the data violate distribution and homogeneity of variance assumptions. In general, the Quasi *F* has proved to be robust.

It has long been traditional in psychology to treat subjects as a random effect in analysis of variance (ANOVA). The rationale is simple: For each experiment, we select from the population a small sample of subjects, but we want our results to generalize beyond this sample. Rarely are we interested in presenting our data as being pertinent only to the particular individuals studied. Both Clark (1973) and Coleman (1964) before him have argued that the logic that compels us to treat subjects as a random effect might also lead us to treat stimulus variation as a random effect; that is, in many situations psychologists should seek generality beyond both the stimuli and subjects of an experiment. This reasoning led Clark to recommend an ANOVA model in which both subjects and stimulus items are treated as random effects. Such models are perfectly possible to create, but have the disadvantage that many hypotheses can no longer be tested using the standard *F* distribution. Instead, models with two random effects often necessitate the use of Quasi *F* ratios, which permit one to form analytic tests on the assumption of the standard linear model. Unfortunately, the exact distribution of the Quasi *F* statistic is unknown. However, when degrees of freedom are appropriately adjusted, the conventional *F* distribution can be used to approximate the Quasi *F* statistic (see Winer, 1971, p. 377).

Clark applied the Quasi *F* analysis to a large body of semantic memory research and demonstrated that treatment effects can be significant when stimulus variation is not considered but nonsignificant when both stimuli and subjects are treated as random effects. Following the publication of Clark's article, the Quasi *F* analysis has become common, in fact, almost obligatory for research in semantic memory.

Clark's arguments about stimulus variation and the Quasi *F* have, however, been virtually ignored in other areas of psychology. In the present article, we argue that the Quasi *F* analysis is appropriate to many areas of psychological research and that its use should not be restricted to psycholinguistic investigation of semantic memory. Furthermore, we demonstrate that the Quasi *F* is quite robust with respect to violations of distribution and heteroscedasticity assumptions.

Applicability of the Quasi *F*

The Quasi *F* analysis is potentially applicable in any experiment that employs a sam-

ple of stimuli, items, or materials drawn from a larger possible population. Exceptions to this exist whenever stimulus variation is totally confounded with subject variation or in case study experiments of a particular item or stimulus set. Excluding these exceptions, psychologists are usually at least implicitly concerned with generality beyond the sample of materials they happen to be using. Most experiments would be considered uninteresting if their results were obtainable for only one subject or even one sample of subjects. Similarly, results that obtain with only one sample of stimulus materials are of questionable interest in psychology. Consequently, psychologists should be as concerned with generality over stimulus materials as they are with generality over subjects.

A few examples might serve to emphasize the variety of situations in which a Quasi *F* analysis is potentially appropriate. Consider first the situation Clark used to illustrate the importance of item variation. Suppose an experimenter wanted to test a theory claiming nouns are more perceptible than verbs. He or she might proceed by selecting a sample of subjects and assessing each subject's perceptibility threshold for a set of 10 nouns and a set of 10 verbs. The experimenter would then calculate the average threshold for nouns and verbs for each subject and would find that every subject exhibited a lower threshold for nouns than for verbs. The original hypothesis that nouns are more perceptible than verbs would appear to be supported by the data, but few psychologists would be convinced by this experiment. After all, the result might only hold for the single sample of 10 nouns and verbs. In fact, the same result could be obtained if only 1 noun were more perceptible than 1 particular verb. So one sees in this simple case that item variation is obviously important whenever items are confounded with (nested within) treatments. Such situations appear in many areas of psychology other than language research.

For example, a number of psychologists have recently been interested in whether human faces are perceived differently from other objects such as buildings. Such experiments compare reaction time or response thresholds to an arbitrarily chosen set of building pictures versus a set of face pictures. Clearly, individual stimulus pictures are nested within treatment condition, and treatment differences could arise simply from differences in particular item perceptibility. A similar situation exists for a clinical psychologist interested in the effects of alcohol on homosexual and heterosexual arousal. A typical experiment might involve a group of subjects given alcohol and a control group given soda water. Subjects might then view a set of slides, each slide depicting a homosexual or heterosexual act. The dependent variable in such an experiment might be the amount of time spent viewing each slide. Again, conclusions regarding the effects of alcohol on type of sexual arousal would be confounded by individual stimuli nested within the homosexual and heterosexual slide groups–confounded in the sense that the main effect of slide type or the interaction with alcohol could arise from one slide or a small number of slides.

Consider next a social psychologist interested in the effects of sex bias in advertising. A typical experiment might involve groups of males and females reading and evaluating a set of job advertisements. The set of advertisements might contain three types: biased for females, biased for males, and neutral. Assuming there were several ads within each of these classes, one again has a situation in which the experimental variables of interest would be confounded with materials. Thus, item variation must be included in the analysis to make the other variables interpretable.

At this point it should be clear that the potential for confounding variables with item variation is present in many areas of psychology and is not at all restricted to psycholinguistic research. In addition to the specific examples we have outlined, it might be noted that at least two other large areas of research should be particularly concerned with the potential confound between experimental variables and stimuli: developmental psychology and studies that employ questionnaires or tests with subscales. Any time a developmental psychologist changes specific materials to suit the age and ability of sub-

jects, he or she entertains the possibility of confounding experimental effects with specific item differences. Similarly, the same confounding is present whenever an educational psychologist or clinician compares people's performance on a pencil-and-paper test. If the scores that enter into the analysis are summed or averaged over items within subscales, then there is a potential confounding of treatments or groups with individual item variation.

All of our examples so far have been concerned with situations in which item variation is directly confounded with treatment variation. Ignoring item variation in these situations leads to results that might not generalize beyond the specific materials of the experiment; and of more importance, the treatment effects might not even generalize across the various stimuli within the experiment. Unfortunately, the problem of item variation confounding treatment effects does not disappear in designs in which stimulus materials cross all treatment conditions. Such experiments are even more common in psychology. For example, a social psychologist might be concerned with the effects of crowding on perceived friendliness. One group of subjects might be jammed tightly into a small room and asked to rate the friendliness of a sample of faces drawn from high school yearbook pictures. A comparison group of subjects might observe the same pictures while seated in a much more spacious, less crowded room. In such a situation the effect of crowding would not be directly confounded with item variation, since both conditions would receive the same items. Effects of crowding would, however, be confounded with the potential interaction of Treatment × Item such that an effect of crowding might be observed on only a small subset of items. If the effect of crowding were obtained for only a few stimuli, it would probably not be of much general interest. In fact, it might well be argued that an effect such as crowding on perceived friendliness would only be of interest if the result were generalizable beyond the idiosyncratic sample of stimuli used in the particular experiment.

Assuming that our examples are sufficient to illustrate the many situations in which stimulus variation can compromise the interpretation of experimental variables, what can be done about this problem? The first step in solving the problem is to include individual stimuli in one's experimental design as opposed to the current practice of summing or averaging over individual stimuli within treatment conditions. The next step is to decide whether to treat the item variations as a fixed or random effect. Obviously, such a decision is not completely arbitrary, but it is beyond the scope of the current article to debate this issue. For our own part, we tend to agree with Clark (1973, 1976) that stimulus variation should be considered a random effect whenever stimuli are arbitrarily drawn from a potentially larger population and whenever it is desirable to generalize the results beyond the set of stimuli used. In other words, *random* for stimuli should mean about the same thing as *random* does for selecting subjects. (For other sides of this issue consult recent articles by Cohen, 1976; Keppel, 1976; Smith, 1976; and Wike & Church, 1976.)

It is important to emphasize that the experimenter's decision to treat stimulus variation as fixed or random has very important consequences for interpretation of the experiment. Consider, for example, an experiment with I treatments, K subjects, and J items nested within treatments. The design for such an experiment is summarized in Table 1 together with the expected values of the mean squares assuming that items are either a fixed or a random effect. The important point to note is that if item variation is a random effect, then the observed estimates of treatment variation will include a component due to item variation, namely, $K\sigma^2_{b(a)}$. Thus, assuming item variation is fixed when it is in fact random will almost always lead to an inflated value for F. Moreover, the inflation will be more severe as the number of subjects is increased. Even replicating the experiment with new subjects and items will not help, since each experiment will produce an inflated F value. In fact, the inflation can be so large that the actual probability of obtaining the observed F can be 40 to 50 times larger than the nominal alpha level, even with only 10 subjects (see Forster & Dickin-

Table 1
Analysis of Variance Table for Experiment Used in Monte Carlo Runs

Source	*df*	Expected *MS*	
		Items fixed	Items random
Treatments (A)	$I - 1$	$J\sigma^2_{ac} + JK(\sigma^2_a)$	$\sigma^2_{b(a)c} + J\sigma^2_{ac} + K\sigma^2_{b(a)} + JK(\sigma^2_a)$
Items within treatments (B(A))	$I(J - 1)$	$\sigma^2_{b(a)c} + K[\sigma^2_{b(a)}]$	$\sigma^2_{b(a)c} + K\sigma^2_{b(a)}$
Subjects (C)	$K - 1$	$IJ\sigma^2_c$	$\sigma^2_{b(a)c} + IJ\sigma^2_c$
A × C	$(I \times 1)(K - 1)$	$J\sigma^2_{ac}$	$\sigma^2_{b(a)c} + J\sigma^2_{ac}$

Total	$IJK - 1$		

son, 1976). In other words, by randomly sampling stimulus materials and then ignoring stimulus variation or treating it as fixed, it is very easy to obtain, inappropriately, significant treatment effects. Conversely, if item variation is not random with respect to treatment conditions, then the Quasi *F* will tend to provide an inappropriately conservative estimate of the true treatment effect. Such an estimate will become more conservative as the number of items within treatments is increased. Thus, the decision to treat item variation as fixed or random is very important and must be consistent with the true state of affairs in the experiment if the resulting statistic is to be meaningful. It is not simply a question of the experimenter deciding to accept more or less generality. Rather, it is a question of choosing a statistical model appropriate to the experiment.

Robustness of the Quasi F

A practical question remains with respect to the use of the Quasi *F* ratio. Does the *F* distribution provide an adequate approximation of the Quasi *F*—one that is useful in realistic experimental situations? There are already several simulations (Davenport & Webster, 1973; Forster & Dickinson, 1976) that suggest the *F* is an acceptable approximation of the Quasi *F* as long as the total degrees of freedom are sufficiently large (> 18). The Satterwaithe (1946) approximation of degrees of freedom for the Quasi *F* leads to a markedly conservative test only if the stimulus and Stimulus × Subjects variance components are quite small. Thus, the Quasi *F* ratio appears to be a reasonable statistic when the normal model holds. However, what happens when one applies the Quasi *F* in the messy world of real data? The ANOVA model has been useful in psychology largely because it is generally robust under violations of the normative assumptions. Psychologists commonly analyze data in which the cells of the design do not have equal variance or the dependent variables are not normally distributed, for example, latency data, percentage data, or situations in which subjects are either correct or incorrect (0–1).[1]

The present article investigates the performance of the Quasi *F* for these typical violations of the ANOVA model. Since the numerator and denominator of the Quasi *F* ratio are linear combinations of estimated mean squares for several sources in the analysis, one might suspect that the violations typically found in psychological data may have serious effects on the accuracy of nominal alpha levels with the Quasi *F*. In particular, we were interested in the possibility that the Quasi *F* ratio would be an extremely conservative test statistic when errors are not normally distributed and when item variances are heterogeneous.

Consequently, we undertook several Monte Carlo studies of the Quasi *F* under a variety of violations of the normal-model assump-

[1] It should be noted that the 0–1 situation is usually avoided by collapsing over a number of stimulus items to obtain a measure with less restricted variation. Use of the Quasi *F* makes it necessary to enter each subject's score on each item, leading to binary scores for individual entries.

tions. The experimental design we used is given in Table 1. In this design 10 subjects were administered each of 12 items from each of four treatment groups.

The data used in the Monte Carlo experiments varied in three ways: in the distribution of data, in the heterogeneity of item variance, and in the combination of values for the variance parameters $\sigma^2_{b(a)}$, σ^2_c, σ^2_{ac}, and $\sigma^2_{b(a)c}$. The experimental data were drawn from distributions that were normal, exponential, log uniform, binary, or log normal. The combinations of item variance within treatment groups were either homogeneous (1,1,1,1) or heterogeneous in the following ratios for the four treatment groups: (1,2,2,5), (1,2,5,10), and (1,2, 5,20). Finally, the basic parameters of the ANOVA model, $\sigma^2_{b(a)}$, σ^2_c, σ^2_{ac}, and $\sigma^2_{b(a)c}$, were varied to approximate a variety of realistic experimental situations (see Table 2). These parameter combinations can be divided into two basic groups: those for which the item and subject variances are large relative to Subject × Item and Treatment × Subject variances (Cases 1–4 in Table 2) and those for which subject variance and Item × Subject variance are relatively large (Cases 6–8 in Table 2). For Case 5, these variances are all equal.

Table 2
Combinations of Variance Parameters Used in Monte Carlo Studies

Case	$\sigma^2_{b(a)}$	σ^2_c	σ^2_{ac}	$\sigma^2_{b(a)c}$
1	9	9	4	2
2	9	9	2	4
3	9	9	4	4
4	9	9	2	2
5	9	9	9	9
6	3	18	1	38
7	2	25	1	28
8	2	12	1	22

Every trial in the Monte Carlo was conducted as follows: (a) values for the random variables, item, subject, Subject × Item, and error were generated using pseudorandom number generators; (b) these components were then added together with the treatment effect and the overall mean to form an observed data point; (c) this set of data was then submitted to an ANOVA; and (d) the probability of obtaining the observed Quasi *F* value or greater for testing treatment effects was recorded using the appropriate degrees of

8	.005	.008	.004	.006	.006

freedom. At the end of 1,000 experiments, the proportions of rejections were tabulated for alpha levels of .05 and .01. Under the null hypothesis, the observed proportions of rejections should be very close to these nominal alpha levels. In our discussion below we follow Clark's (1973) notation so that Quasi $F = (MS_A + MS_{B(A)C})/(MS_{AC} + MS_{B(A)})$, $F_1 = MS_A/MS_{AC}$, and $F_2 = MS_A/MS_{B(A)}$.

Table 3 shows the performance of the Quasi F under various violations of the homogeneity of variance assumption. The first column of Table 3 illustrates the rejection rate of the Quasi F in the situation of homogeneous item variances. In general, the Quasi F performs quite well under the normal model but tends to be slightly conservative. Columns 3–5 of Table 3 show the performance of the Quasi F under various violations of the homogeneity of variance assumption up to a 20:1 inequality among treatment variances. For Cases 1–4 in which item and subject variances are large relative to the interaction components, there is a trend for heteroscedasticity to give slightly more rejections than the nominal alpha, but for Cases 6–8 heteroscedasticity makes the statistic slightly conservative. Overall, the Quasi F appears quite acceptable in the face of rather severe departures from the homogeneity of variance assumptions.

Next, we examined the Quasi F in situations in which the data were drawn from a variety of common distributions. Monte Carlo results of the Quasi F for the eight combinations of variance parameters and five types of distributions are presented in Table 4. Inspection of the table reveals that the Quasi F is conservative although not painfully so. When item and subject variances are relatively large (Cases 1–4), the Quasi F tends to be very slightly conservative; it is somewhat more conservative in Cases 6–8 in which subject and Item × Subject variances are relatively large.

Averaging over all cases and looking at the mean rejection rates reveals that nonnormality makes the Quasi F somewhat more conservative than it is with the normal distribution. The best performance is obtained with the normal and log-uniform distributions, the worst with the log-normal distribution. The exponential and 0–1 distributions tend to be intermediate. Among these distributions

Table 4
Observed Proportions of Rejections (1,000 Runs) in Null Case for Quasi F *for Five Error Distributions*

8	.005	.003	.005	.004	.005
M	.093	.007	.008	.004	.005

the log normal is the closest in approximating the shape of reaction time distributions typically observed in psychological data; consequently, it may be advisable to take logs of reaction times to normalize the data. Finally, it should be noted that although the Quasi *F* performs well, on occasion the observed rejection rate is only one tenth of the nominal alpha. The relative discrepancy between real and nominal alpha is of course greater when the nominal alpha is smaller.

The results of our simulations make it clear that the Quasi *F* is a useful and robust test. Even at its worst, the test is not outlandishly conservative. For example, a test using a nominal alpha of .05 would almost certainly have a real alpha between .02 and .06. For most researchers this level of uncertainty about a decision is perfectly acceptable.

Power

Let us briefly consider the question of power for the Quasi *F* statistic as contrasted to the *F* statistic obtained by assuming stimulus variation to be a fixed effect. It is, of course, difficult to compare directly the power of these tests unless one assumes a constant experimental circumstance. In other words, assume a situation in which there is a real difference underlying the treatment conditions and an experiment with *K* subjects and *J* items. The question of interest is how do the Quasi *F* and the *F* differ in their ability to detect the difference.

It is relatively easy to evaluate power for a conventional *F* by calculating a noncentrality parameter (NCP) from

$$\mathrm{NCP}(F_1) = 2Kd^2/\sigma^2_{\mathrm{ac}},$$

where d = difference in treatment means. Given the NCP and the degrees of freedom for the experiment (in our situation, 3 and 27), it is possible to look up the theoretical probability of detecting the observed treatment effect using tables of the noncentral *F* (Tiku, 1967). The situation is not so straightforward with the Quasi *F*. However, it is possible to obtain a noncentrality parameter by using

$$\mathrm{NCP}(\text{Quasi } F) = 2JKd^2/[K\sigma^2_{\mathrm{b(a)}} \times J\sigma^2_{\mathrm{ac}} + \sigma^2_{\mathrm{b(a)c}}].$$

The degrees of freedom can then be estimated by the observed average for the 1,000 simulated experiments. Using these estimates

Table 5
Observed Versus Theoretical Power of the Quasi F

one can again consult Tiku's tables to obtain an estimate of the power of the Quasi F. Table 5 illustrates the observed and theoretical power of the Quasi F as contrasted to the power of F_1 for two representative conditions of the ANOVA parameters (Cases 3 and 7).

Two conclusions are apparent from the table. First, the theoretical power of the Quasi F is in good accord with the observed probability of rejection. Again the Quasi F is a reasonable statistic, this time in terms of power. The second conclusion is somewhat more troublesome although quite expected: The Quasi F has considerably less power to detect a given treatment effect than does F_1. One should remember that the columns of Table 5 illustrate different situations. The powers given for Quasi F are those when item variation is in fact random; the powers for F_1 are those when item variation is in fact fixed. Inspection of the expected mean squares in Table 1 reveals that if items within treatments are random it will be more difficult to discern treatment differences than if items are fixed.

Clark (1973) has suggested the use of the statistic $F'_{\min}$ whenever mean squares of the Quasi F are difficult to compute—for example, when the data contain missing observations. For the design discussed in the present article, $F'_{\min}$ is as follows:

$$F'_{\min}(i, j) = MS_{\mathrm{A}}/[MS_{\mathrm{AC}} + MS_{\mathrm{B(A)}}],$$

where i is the number of treatment levels minus one and

$$j = [MS_{\mathrm{AC}} + MS_{\mathrm{B(A)}}]^2 \Big/ \left[\frac{MS^2_{\mathrm{AC}}}{df_{\mathrm{AC}}} + \frac{MS^2_{\mathrm{B(A)}}}{df_{\mathrm{B(A)}}}\right].$$

The statistic $F'_{\min}$ is also equivalent to

$$F'_{\min}(i, j) = \frac{F_1 \cdot F_2}{F_1 + F_2}.$$

Since $F'_{\min}$ is always less than or equal to Quasi F, its computational advantage is to be weighed against the obvious disadvantage of its conservatism. In the recent Monte Carlo study of Forster and Dickinson (1976), the observed alpha level for $F'_{\min}$ was in fact very close to the nominal level. However this study was done with a small range of "nuisance parameter" values and assumed the normal model. Consequently, the generality of their results is limited. The observed alpha level of $F'_{\min}$ for a nominal alpha of .05 in the conditions of our study is presented in Tables 6 and 7. Inspection of the tables shows that $F'_{\min}$ is fairly well behaved for Cases 1 to 5, but is markedly conservative for Cases 7 and 8. Clark (1976) has pointed out one case for which it is possible to compute an exact alpha level for $F'_{\min}$, namely, when there are two treatment groups. In this case, the square root of $F'_{\min}$ is distributed as a t test between two means with unequal variances. In such a situation it is of course perfectly reasonable to use $F'_{\min}$.

Imhoff (1960) generalized Scheffé's two-way mixed model to a completely crossed

three-way mixed model with two random effects and one fixed effect and derived an exact test based on Hotelling's T^2 for the hypothesis of no fixed main effects. Again, the test is perfectly appropriate but of limited applicability.

Discussion

Our simulations have shown that the Quasi *F* ratio is a very reasonable statistic. It appears to be slightly conservative, but is robust with respect to violations of the normal model. In short, the Quasi *F* is quite serviceable in realistic experimental situations. There is no doubt that the Quasi *F* is a useful test whenever inferences beyond the specific stimuli and subjects of an experiment are sought. However, some experimenters will be concerned about being penalized by the conservative nature of the test. First, it should be noted that the Quasi *F* is not markedly conservative with respect to the nominal alpha level. Second, experimenters who use the Quasi *F* should feel free to break the stranglehold of $\alpha = .05$. Both experimenters and editors should be willing to accept a result that is significant at the .06, the .07, or even the .10 level. It is far better to relax slightly the nominal level of rejection than to persist in the misuse of a statistic such as F_1 in which the nominal alpha has virtually no meaning.

What about situations in which a fixed effect design is appropriate, for example, when sampling constraints become so stringent that the experimenter cannot treat the stimulus variation as random? Even in these situations the experimenter should not totally ignore stimulus variation. Rather, stimulus variation should still be entered into the design as a fixed effect (as opposed to collapsing over stimuli to obtain an average score for each subject). With this precaution it is at least possible to evaluate the contribution of stimulus variation. In a design with stimuli nested in treatment conditions the experimenter should test for the significance of stimulus variation. When the same stimuli appear in all treatment conditions, the Treatment × Stimulus interaction should be evaluated. If it turns out that stimulus variation or the Treatment × Stimulus variation is not significant, then general confidence in the treatment effect is greatly increased. On the other hand, if these terms are significant, conclusions about the treatment effect might not even generalize across the sample of stimuli used in the experiment. In either case the experiment does not generalize beyond the particular stimulus sample, but if the appropriate item variation term is small, the experimenter can at least have confidence that the treatment effect is not due to a few deviant items.

Another alternative for experiments in which stimuli are a fixed effect is to replicate the experiment using a new sample of subjects and new stimulus materials. Many experimenters already use this procedure. For example, an experimenter might use two lists of words or alternate forms of a test. In such cases it is often possible to use the Quasi *F* test by treating both subjects and replica-

tions as random effects even if the experimenter does not want to analyze responses to individual stimuli. Demonstrating that a result is reliable across replications clearly enhances the credibility of the finding.

The above remarks pertain to a stimulus effect that must be treated as a fixed source of variation. As we have previously noted, it is much more common to want generality across both subjects and stimuli. In such circumstances the Quasi F is both an appropriate and a robust statistic. However, there is a final note of caution: Our discussion of the Quasi F ratio is itself limited in generality. We have examined the performance of only one type of Quasi F statistic. More work is needed to explore the class of Quasi F tests before psychologists proceed to use every imaginable form of concocted F ratio. In the meantime, the robustness of the Quasi F in our simulations is quite promising and suggests that more general use of such tests would greatly increase the reliability of the published data base.

The Detection of Deception

David T. Lykken
Department of Psychiatry
University of Minnesota Medical School

The polygraph (lie detector) test has an accuracy of 64% to 71% (against a chance expectancy of 50%) when the polygraph charts are scored blindly and are thus uninfluenced by clinical impressions of the subject or of the evidence against him. The lie test is biased against truthful subjects, at least half of whom may be erroneously classified as *deceptive*. These conclusions, based on two recent studies of lie test validity in real-life applications, corroborate an earlier critical analysis of the assumptions on which the lie detector is based. Since, in the field, most subjects tend to "fail" the lie test whether they are truthful or deceptive, the method more often detects lying than it does truthful responding. However, it seems probable that deceptive subjects could be taught to artificially augment their polygraph responses to the so-called control questions and thus to avoid being scored as deceptive. The review by Podlesny and Raskin conveys the impression that the lie test is already highly accurate and that addition of other response variables might enhance its validity even further. This impression is erroneous and dangerously misleading.

The recent survey by Podlesny and Raskin (1977) conveys an impression that existing lie detector techniques are based on reasonable psychophysiological theory and are supported by experimental findings of impressive validity. If current techniques already permit valid detection of deception in from 88% to 96% of subjects tested (Podlesny & Raskin, 1977, p. 787), even without the 9 or 10 new variables that the authors describe as "particularly promising" (p. 797), then the further research they call for might be expected to produce a virtually infallible lie detector. Who could then object to the growing trend toward lie detector screening of employees or the admission of lie test evidence in courts (Lykken, 1974)? If the polygraphist is correct 96% of the time even "on hardened criminals behind bars" (Raskin, quoted in Dunleavy, 1976), then allowing a fallible jury to deviate from the polygraphist's judgment—indeed, using a jury at all—can only diminish the accuracy of verdicts based solely on the lie test. In view of the claims that other exponents of the lie detector have been making over the years, it strikes one as curious that such implications of these claims seem never to be spelled out. If the lie test is 96% accurate, at least as Raskin performs it, and if Podlesny and Raskin are correct in suggesting that the few existing studies, most of which are defective in design, have as yet failed to exploit the potential of a host of "promising" additional test variables, it appears that we are dealing not only with the most valid psychological test ever devised but also with potentially the most important social problem ever to issue from the psychological laboratory.

Theory of the Lie Detector Test

In an earlier treatment (Lykken, 1974), I attempted to show that the theory of the lie test is so naive and implausible that one should demand especially strong empirical evidence before accepting claims of extremely high validity. Podlesny and Raskin (1977)

Table 1
List of Questions Used in Raskin's Lie Dectector Test (Note 1)

1. Were you born in Hong Hong? (Yes)
2. Regarding the stabbing of Ken Chiu, do you intend to answer truthfully each question about that? (Yes)
3. Do you understand that I will ask only the questions we have discussed? (Yes)
4. During the first 18 years of your life, did you ever hurt someone? (No)[a]
5. Did you cut anyone with a knife on Dumfries St. on January 23, 1976? (No)[b]
6. Before 1974 did you ever try to seriously hurt someone? (No.)[a]
7. Did you stab Ken Chiu on January 23, 1976? (No)[b]
8. Is your first name William? (Yes)
9. Before age 19, did you ever lie to get out of trouble? (No)[a]
10. Did you actually see Ken Chiu get stabbed? (No)[b]

Note. Defendant's answers are in parentheses. If the autonomic disturbance associated with the relevant questions tends to be greater than that associated with the paired control questions, the subject is diagnosed as ***deceptive***. Since it is assumed that an innocent subject is more concerned by the control than by the relevant questions, larger responses to the former are interpreted as evidence that the answers to the latter are ***truthful***.
[a] Control question.
[b] Relevant question.

dismissed my analysis on the grounds that it "assumed that control questions are designed to be answered truthfully by the subject and that a lack of difference in magnitude of reactions to control and relevant questions constitutes the basis for a truthful result. Both of these assumptions are factually incorrect" (p. 787). The second of these alleged assumptions does not appear in my article (Lykken, 1974), which, on the contrary, correctly states that "the examiner is advised to classify tests that give intermediate [i.e., lack of difference] scores as 'inconclusive'" (p. 730). With respect to the first assumption, I stated accurately that "the control question is chosen with the intention that it will elicit an emotional response from the subject, preferably a response involving the attitude of guilt, for example, 'Can you remember ever stealing anything before you were 18 years old?'"; I added, "It is expected that the subject will answer it truthfully" (pp. 729–730). I should have also explained that many polygraphists claim that they can devise control questions, not concerned with the central issue of the interrogation, that the subject will answer deceptively and that will derive their guilty emotional impact from that attempted deception. Instead of somehow invalidating my analysis, this addendum reveals even more clearly the naiveté and implausibility of the theory of this control question lie test, as is illustrated below.

Let us consider an actual lie detector test administered by Raskin to a criminal defendant accused of homicide by stabbing (*Proceedings at Trial*, Note 1). The questions employed in that test are listed in Table 1. Questions 5, 7, and 10 are the relevant questions pertaining to the incident; Questions 4, 6, and 9 are the control questions. The scoring procedure used by Raskin involves comparing the polygraph responses associated with each of the three adjacent pairs of relevant and control questions and assigning a numerical score to each pair, for example, −3 if the relevant question elicits a much larger response than the control, +3 if the control response is much the larger, and 0 if there is no difference. This is done for each of the three or four polygraph channels employed and for each of the two or three repetitions of the question list that may be used. If the sum of these scores is, say, +6 or higher, the subject is said to have been truthful; if the sum is −6 or lower, he is diagnosed as deceptive. In the 10% or so of cases in which the total score is near 0, the test is considered inconclusive.

It should be pointed out that a polygraph chart is very complex and that considerable subjectivity may influence the polygraphist's evaluation of the autonomic disturbance associated with a particular question. But let us assume that objective and consistent rules for evaluating polygraphic response amplitude were available and that some means were found to insure that they were followed faithfully by polygraphists in practice. Then, referring to Table 1, if this defendant tended to give larger autonomic responses to the relevant questions (5, 7, and 10) than he did to the

controls (4, 6, and 9), he would be classified *deceptive*. If his responses to the controls tended to be larger, he would be classified *truthful*. The question is whether it is reasonable to expect that such a test might have 96% validity.

Podlesny and Raskin (1977) explained, referring to the control questions, that "the subject is very likely to be deceptive to them or very concerned about them" (p. 786). I suspect that this defendant's *no* answers to Questions 4 and 9 were technically untrue because most people have "hurt someone" or have "lie[d] to get out of trouble" prior to the age of 20. But I do not know that these answers were false in this case and neither does Raskin. Indeed, it is quite possible that this defendant thought he was telling the truth in both instances, interpreting *hurt* to mean something serious like the mortal stab wound he was accused of inflicting and *trouble* to mean something serious like being charged with murder. In the case of the second control question (Question 6), I think it most likely that the subject's answer was entirely truthful. (I had never tried to "seriously hurt someone" prior to 1974!) A moment's reflection makes it plain that no polygraphist can reasonably claim to be able routinely to construct control questions that are somehow guaranteed to elicit deceptive answers from the subject. If Podlesny and Raskin wish to claim that this is an essential feature of a properly administered lie test and that any analysis of the theory of the test must assume that the control responses are known lies, then further consideration of the lie test is pointless because no such test could possibly be devised except under extraordinary circumstances (viz., if the examiner happens to have proof of additional crimes committed by the subject but which the subject wishes to deny).

Clearly the purpose of the control question is that "it will elicit an emotional reaction from the subject" (Lykken, 1974, p. 730) or that the subject will be "very concerned" about the questions (Podlesny & Raskin, 1977). The emotional reaction occurs because the subect's answer is deceptive, because he is truthful but is ashamed to make that admission, or merely because the question touches on some painful or embarrassing issue. The issue to be decided, then, is whether a larger autonomic response to the relevant question (e.g., "Did you stab Ken Chiu on January 23, 1976?") than to the control question (e.g., "Before 1974 did you ever try to seriously hurt someone?") should plausibly be taken as strong evidence that the subject's answer to the relevant question is a lie.

To state it more generally, does the control question really function as a control in the usual scientific sense of that term, that is, does the autonomic response to the control question provide a reasonable estimate of what the subject's response to the relevant question ought to be if he is answering truthfully? Alternatively, one might ask whether the control response yields a reasonable estimate of what the relevant response should be if the answer to the relevant question is deceptive. This is the basic unavoidable assumption of the lie detector test, and it seems to me to be patently implausible. By what prescience did Raskin know how concerned the defendant was about Question 6? And yet he was obliged to titrate this concern with exquisite precision in advance of the test proper because his scoring assumes that the response to Question 6 will be greater than the response to Question 7 if the answer to Question 7 is truthful but that the response to Question 7 will be greater than the response to Question 6 if the relevant answer is a lie. One can imagine scenarios, all perfectly plausible, that might have led this defendant to be extremely, moderately, or negligibly concerned about the three control questions listed in Table 1. As a general rule, one would expect most subjects to be more concerned about the relevant questions than about the controls, whether they answer deceptively or truthfully, because it is the relevant questions that refer directly to the source of their immediate jeopardy. Thus, one would expect most subjects to tend to "fail" lie detector tests in real-life situations, and this bias against the truthful subject is just what the data confirm, as is shown below.

On the other hand, no psychologist ought to rule out the possibility that some criminal defendants, even though guilty as charged, might develop habituation to, or psychody-

namic defenses against, specific references to their crime and thus might be less responsive to the relevant than to the control questions so as to "pass" the lie test. A sophisticated criminal might know enough to augment his own reactions to the three control questions by flexing his toes, tensing his diaphragm, or biting his tongue at the appropriate moments. No good studies of the success of such countermeasures in real-life situations are available. Polygraphists claim that they could not easily be deceived in this way, whereas, on the contrary, I claim that I could train guilty suspects to successfully "beat" the control question lie test.

In the above case, Raskin testified that the defendant had in fact responded most strongly to the control questions and was truthful. The jury disagreed, finding the defendant to be guilty (*Proceedings at Trial*, Note 1). Did an innocent suspect in this instance behave in accordance with the assumptions of the lie detector or did a guilty suspect beat the test? One must turn to systematic validity studies to determine how the lie test, however implausible, actually works in practice.

Accuracy of the Lie Detector in the Field

Although Podlesny and Raskin (1977) acknowledged that "there are many problems inherent in laboratory investigations of [psychophysiological detection of deception]" (p. 782), they stopped short of asserting that meaningful estimates of lie test accuracy in any field application must be obtained from appropriate field studies. Yet this clearly is the only reasonable conclusion. Giving lie tests to students who have enacted mock crimes or to prisoners who have competed for money prizes may be useful for other purposes but will not provide adequate predictions of what can be expected in real-life criminal investigation. Raskin's laboratory study using prison inmates (Raskin & Hare, 1978), for example, involved a deceptive context in which genuine and realistic fear of failure played no role whatever (surely the fear that one might fail to win a $20 prize is qualitatively different from a criminal suspect's fear that he may end up in prison). Thus, when one looks for evidence concerning the accuracy of the lie test in its intended application, one must confine one's attention to real-life studies in the field.

Secondly, since interest lies in the contribution of the polygraph to the detection of deception rather than in the clinical judgment of the examiner, one must also exclude all studies in which the lie tests were scored globally, still a common practice among many polygraphists. With this method of scoring, all the examiner knows about the subject, the evidence against him, his demeanor during the examination, and the like is compounded in the mind of the examiner with the actual polygraph results by some unspecified subjective formula to produce the final judgment of deceptive or truthful. In the Bersh (1969) study, for example, the criterion of guilt or innocence was the majority verdict of four experienced prosecutors based on their reading of the completed files of 243 criminal suspects. These judges split 2:2 on 27 cases, leaving 216 that could be usefully compared to the polygraphist's previous diagnosis of deceptive or truthful. The polygraphists agreed with the criterion in nearly 88% of these cases. But because at the time of the examination the polygraphists knew what evidence was then available and were able to interview and observe the suspects at some length, one must suppose that their decisions about the suspects' guilt or innocence would have been substantially more accurate than chance expectancy (i.e., 50% agreement with the criterion) even if they had ignored the polygraph results entirely. In fact, one cannot be certain that the polygraph itself contributed at all to the accuracy rate that Bersh reported. Another part of the U.S. Army study from which Bersh's data came ("Use of Polygraphs," 1975) examined the agreement between the original polygraphist's decision and that of other polygraphists who read the same charts blindly. Agreement was low (kappa coefficients ranged from .15 to .51), indicating that the polygraph data could not have contributed much to the accuracy of the original examiner's judgments. Since field studies using blind scoring of polygraph charts do not show nearly so high an ac-

curacy, Bersh's findings must be set aside as ambiguous and almost certainly are an overestimate of the validity of the polygraph test per se.

Clinical Versus Actuarial Lie Detection

Polygraphists who endorse the use of global judgments stress that it is the examiner, not the polygraph, who functions as the lie detector. Trade journals such as *Polygraph* or *Journal of Polygraph Science* are full of unsubstantiated claims concerning interview behaviors said to be indicative of guilt or of innocence (Lykken, 1978). Is it fair, therefore, to insist on separate assessment of the contribution made by the polygraph charts themselves to the accuracy of the examiner's decisions?

The history of validity studies of projective techniques like the Rorschach Inkblot Test provides a limited but useful analogy. It appears that certain talented individuals, observing a subject responding to the Rorschach cards, are often capable of drawing clinical inferences of remarkable accuracy. But the majority of Rorschach test administrators are not nearly so accurate, and attempts to objectify the cues or reasoning employed by the skillful few have met with limited success. There undoubtedly are certain police detectives and polygraph examiners who are similarly skillful in determining, by subjective evaluation of clinical observations, which suspect is lying and which is not. It is possible that more polygraphists might develop such skills if they were given formal training in psychology. But it is most doubtful that a trial judge would ever admit into evidence the clinical opinion of some self-styled "veracity expert," in the form, "I have observed this defendant, considered his story and the relevant evidence, and in my opinion he is (or is not) telling the truth," even if he were a fully accredited psychologist or psychiatrist. What business concern would employ someone who claims to be able to detect lying intuitively, through observing interview behavior, and would allow him to screen prospective employees for honesty or to determine which current employees are stealing from the company and should be fired?

Clearly, the mystique of the lie detector, the reason why the polygraph test is taken seriously by some courts, by business, and by the general public and why the lie detector industry is flourishing in this country, is wholly dependent on the technological or scientific aura of the polygraph itself. It is conceivable that some polygraph examiners are skillful clinical lie detectors, but this issue is of negligible scientific or social importance. What is important is whether, as Podlesny and Raskin contend, the polygraph test is an objective, teachable method of extraordinary validity.

The Evidence

Fortunately, subsequent to my 1974 review, two field studies appeared that provide estimates of lie test accuracy under real-life conditions, when the polygraph charts are scored blindly by someone other than the examiner who administers the test. Both authors were and are professional polygraphists and certainly were not hoping for unfavorable results. Horvath (1977) had 10 trained polygraphists independently score charts taken from the files of a large police department. There were 28 suspects who had subsequently been cleared by the confession of another person; 28 others had themselves confessed some time after the original testing. The 10 experienced polygraphists agreed with each other about 89% of the time, indicating presumably that they followed similar rules of chart interpretation. But the validity of their scoring was not nearly as impressive as their interjudge agreement; the 560 blind scorings were correct only 64% of the time. My analysis of the lie test suggested that it should discriminate against the truthful subject or at least against those subjects with sense enough to realize that the relevant questions are more important to their fates and more threatening than the (essentially irrelevant) control questions. This expectation was strongly confirmed by the Horvath study in which the known liars were correctly scored as deceptive about 77% of the time (against a chance expectancy of 50%), whereas the known truthful suspects were incorrectly

Table 2
Summary of Available Data on Accuracy of Control Question Lie Test Using Blind Scoring

Item	Horvath (1977)	Barland and Raskin (Note 2)	
	Verified	Reported	Corrected[a]
Number guilty	28	40	40
Number innocent	28	11	40
Percent guilty	50%	78%	50%
Percent deceptive	63%	88%	76%
Percent correct (hit rate)	64%	86%	71%
False negative rate	31%	17%	5%
False positive rate	39%	13%	36%
Guilty called truthful	23%	3%	3%
Innocent called deceptive	49%	55%	55%

Note. Observe the high proportion of innocent suspects misclassified as deceptive and the associated high rate of false positive classification.
[a] To provide meaningful estimates of accuracy and error rates, the data of Barland and Raskin had to be corrected for the high base rate (78%) of criterion-guilty subjects. This was done by assuming Raskin would have made the same proportion of errors (55%) if 40 innocent suspects had been tested as he made on the 11 innocent suspects who were tested, thus yielding a standardized base rate of 50% criterion-guilty subjects.

scored as deceptive half of the time, giving a false positive rate of 39%.

The second recent study (Barland & Raskin, Note 2) employed Bersh's method of using a panel of lawyers or judges to determine, from all evidence excluding the lie test results, which suspects were guilty or innocent. Barland administered the tests, and the charts were then scored independently by Raskin. A majority of the criterion judges agreed on 64 of the 92 cases tested, but 13 (20%) of these 64 tests were classified *inconclusive* by Raskin. On the remaining 51 tests, Raskin's scoring agreed with the criterion on 44 of them, a hit rate of about 86%, which the authors reported as their estimate of field accuracy. However, 39, or 78%, of these same cases were guilty by the criterion, which means that one might have achieved a hit rate of 78% on this sample just by calling everyone deceptive (Raskin in fact scored 88% as deceptive; see Table 2). Clearly, nonarbitrary accuracy estimates can only be obtained either by equalizing the numbers of guilty and innocent suspects and assuming Raskin would have been correct in the same proportion of 40 cases as he was in the actual 11 cases (see right-hand column of Table 2) or by considering the fate of the guilty and innocent subjects separately. Raskin scored 39 of the 47 guilty suspects as deceptive, 1 as truthful, and the remaining 7 as inconclusive. But only 5 of the 17 innocent suspects were correctly scored as truthful; 6 were called deceptive and 6 inconclusive. Had this study been designed like Horvath's (1977), with half the subjects guilty and half innocent, then—excluding inconclusives—one might expect about 71% hits overall and a false positive rate of 36%, very similar to the 39% false positives in the Horvath study. Although Raskin correctly diagnosed all but 1 of the guilty subjects as deceptive (not counting the 7 inconclusives), he did this at the expense of calling 55% of the innocent suspects deceptive also.

These two studies constitute the only evidence available concerning the accuracy of the control question lie test administered under real-life conditions and scored to exclude the influence of clinical judgment (or prejudice) and thus to provide some idea of the accuracy of the polygraph test itself. And the two studies agree quite well, showing an accuracy of from 64% to 71%, against a chance expectancy of 50%, and showing that of those who fail the test, 36% to 39% will be false positive, truthful subjects (assuming that half the subjects tested are innocent). Raskin failed a higher proportion of his subjects than Horvath's polygraphists did: 76% versus 63% if one again assumes that both

studies used equal numbers of guilty and innocent subjects. Therefore, Raskin called a higher proportion of both the guilty and the innocent subjects deceptive. Podlesny and Raskin (1977) cited the Barland and Raskin (Note 2) study, but they did not mention the actual results; the Horvath (1977) study was not even cited. Instead, my arguments (Lykken, 1974) predicting that the lie test should show a high rate of false positives in real-life applications are supposedly refuted by a referral to the results of two mock crime laboratory studies by Raskin and his colleagues (Podlesny & Raskin, 1977, p. 787).

Conclusions

Thus one sees that the control question lie test is not 88%, 90%, or 96% accurate in real-life applications, but rather is in the neighborhood of 64% to 71% accurate when standardized for a chance expectancy of 50%. The actual false positive expectancy is not 8%, 4%, or 2%, but is more on the order of 36%–39%. A skillful examiner who is willing to call as many as three fourths of all subjects deceptive can detect most liars (assuming the subjects are not equally skilled at beating the test), but he will at the same time call most of the truthful subjects deceptive also. An interesting research question not mentioned by Podlesny and Raskin is whether many deceptive subjects could be trained to beat the special form of lie test that they advocate. Any intelligent criminal could easily be taught to identify the three control questions and instructed to augment his autonomic reactions to these questions in a variety of covert ways. In fact, I venture another prediction; let me train guilty suspects in Barland and Raskin's next field study, and I predict their false negative rate may approach what their false positive rate is right now.

Truth and Deception: A Reply to Lykken

David C. Raskin
University of Utah

John A. Podlesny
Western Reserve Psychiatric Habilitation Center
Northfield, Ohio

In response to Lykken's critique, scientific evidence is presented that shows that control question tests of deception have an accuracy of approximately 90% in the field situation and are highly effective with both innocent and guilty subjects. Lykken's erroneous representation of the theory of such tests is corrected, and his selective and misleading presentation of the scientific data is rectified. The proper interpretation and application of control question tests in the criminal justice context are described, and the tests are shown to be highly beneficial to innocent defendants, the judicial process, and society in general.

In a critique of our recent article (Podlesny & Raskin, 1977), Lykken (1979) attempted to discredit our theoretical analyses and conclusions by using intuitive and speculative arguments and by selective and misleading descriptions of the existing data and literature. Lykken also made bold claims about his ability to train people to "beat" the control question test, and he presented a misleading description of a polygraph test conducted by Raskin in a criminal case. This article attempts to correct those errors with a careful examination of the theory, the scientific data and literature, and the applications of control question tests for truth and deception.

Theory of Control Question Tests

In spite of 5 years of contact with the literature and with concepts of control question tests (see Raskin, 1978), Lykken still does not understand the simple, basic theory. The theory holds that, following a detailed pretest interview, a guilty subject will show relatively stronger autonomic responses to the relevant questions and that an innocent subject will show relatively stronger responses to the control questions, which deal with acts of the same general nature as those covered by the relevant questions. The control question is a stronger stimulus for the innocent subject because he knows he is truthful to the relevant questions; he has been led to believe that the control questions are also very important in assessing his veracity; the manner of explaining the control questions to him and their wording have elicited a *no* answer; and he is either deceptive in his answers, very concerned about his answers, or unsure of his truthfulness because of the vagueness of the questions and problems in recalling the events. His concern about being diagnosed as deceptive produces autonomic reactions to the controls. There is no attempt to "titrate this concern with exquisite precision in advance of the test proper" (Lykken, 1979, p. 49). Control questions are emphasized to all subjects during the pretest interview and immediately following each chart (Podlesny & Raskin, 1978; Raskin & Hare, 1978).

Lykken was simply wrong when he stated that "the theory of the test must assume that the control responses are known

lies" (p. 49) and that the purpose of the control question is to provide an estimate of the subject's autonomic response to a relevant question answered truthfully. We have never stated that the control question should "function as a control in the usual scientific sense of that term" (Lykken, 1979, p. 49). This statement describes the function of noncritical items in a guilty knowledge test, and it seems to indicate that Lykken does not understand the basic difference between guilty knowledge tests and control question tests. The actual purpose of the control question is to provide a stimulus that will produce a stronger autonomic reaction than the relevant question when the subject is innocent, thereby providing a positive identification of innocent subjects.

Empirical Issues

Our 1977 review (Podlesny & Raskin, 1977) dealt almost exclusively with laboratory research and made suggestions to maximize its generalizability to field applications, but Lykken arbitrarily dismissed the utility of laboratory experiments in estimating the accuracy of field detection of deception. This position betrays a profound lack of understanding of the scientific method and the value of controlled experimentation and diversity of evidence (Hempel, 1966). As we pointed out (Podlesny & Raskin, 1977), the best strategy "is to employ laboratory research that simulates field-deceptive contexts as closely as possible, along with field validation" (p. 784). We have used prisoners, criminal suspects, very realistic mock crimes (so realistic that some subjects decline to participate in the mock crime), substantial motivation, and potential loss of reward or punishment. In laboratory experiments with subjects recruited from the community by newspaper ads, with prison inmates, and with diagnosed psychopaths, we have consistently obtained accuracy rates above 90% (Podlesny & Raskin, 1978; Raskin & Hare, 1978; Rovner, Raskin, & Kircher, Note 1), and such findings are very useful in the scientific enterprise of estimating accuracy in real-life situations.

Table 1
Percentage of Correct Decisions in Five Studies With Blind Interpretations of Polygraph Charts Obtained From Verified Guilty and Innocent Subjects

Study	Guilty	Innocent
Horvath & Reid (1971)	75[a]	83[a]
	89[b]	94[b]
Hunter & Ash (1973)	88	86
Slowik & Buckley (1975)	85	93
Wicklander & Hunter (1975)	95	93
Raskin (Note 3)	93[c]	69[c]
	100[d]	95[d]
Combined results	90	89

[a] Decisions were made by intern examiners.
[b] Decisions were made by experienced examiners.
[c] Evaluation was nonnumerical.
[d] Evaluation was numerical.

Lykken was correct in emphasizing the need for validation studies with criminal suspects using blind evaluation of polygraph charts. Unfortunately, he provided misleading interpretations of the two studies that he selected, and he failed to mention five published studies that meet his criteria but provide strong evidence against his position. Lykken also failed to mention that in the Horvath (1977) study the original examiner was 100% correct and the cases were all verified by confessions. It has been pointed out (Raskin, 1978) that the unusually low level of accuracy attained by Horvath's blind evaluators was very likely due to their lack of formal training in systematic chart interpretation and their heavy emphasis on overt behavior symptoms rather than on systematic chart interpretation. Therefore, the Horvath study is of little value in assessing the accuracy of decisions based on systematic chart interpretation.

Lykken (1979) was incorrect when he stated that the Horvath (1977) and Barland and Raskin (Note 2) studies "constitute the only evidence available concerning the accuracy of the control question lie test administered under real-life conditions and scored to exclude the influence of clinical judgment (or prejudice) and thus to provide some idea of the accuracy of the polygraph test itself" (p. 52). There are five other published

studies that meet Lykken's criteria of blind interpretation of confirmed polygraph charts from criminal suspects. The findings of these studies are presented in Table 1. The mean accuracy rates of 90% correct on guilty suspects and 89% correct on innocent suspects were based on a total of 1,204 independent decisions obtained by blind interpretation of polygraph charts by 55 different polygraph examiners. The data from Horvath and Reid (1971) show that experienced examiners are more accurate, and the Raskin (Note 3) data clearly demonstrate that the use of a relatively objective, systematic method of quantified chart interpretation yields significantly higher accuracy rates, which approach 100%.

The reliability of the numerical scoring system is extremely high. Using the numerical system with blind chart interpretation, we obtained a mean correlation of .86 for the 15 pairings of six independent evaluators (Barland & Raskin, 1975), a .91 correlation between numerical scores and 99% agreement with the examiner's original decisions on 102 criminal suspects (Barland & Raskin, Note 2), a .97 correlation between numerical scores and 100% agreement with the original examiner's decisions in a laboratory study (Podlesny & Raskin, 1978), and 95% accuracy and 100% agreement with decisions made 2 years before in a laboratory study of criminals and psychopaths (Raskin & Hare, 1978).

The extensive and consistent findings just described demonstrate the very high reliability and validity of blind chart interpretation when it is performed by competent examiners who have been adequately trained in chart interpretation and who do not make decisions based on the questionable procedure of observing behavior symptoms. The latter procedure has been shown to be ineffective in assessing truth and deception (Podlesny & Raskin, 1978; Raskin, Barland, & Podlesny, Note 4), and it is not surprising that examiners trained to rely on behavior symptoms instead of polygraph charts produce results hardly better than chance (Horvath, 1977).

In addition to the Horvath (1977) study, Lykken placed great weight on the high false positive rate in the Barland and Raskin (Note 2) study. In this study, as in field studies of lie detection generally, it was necessary to substitute criteria of guilt or innocence in place of factual knowledge. The two major criteria were decisions of a panel of legal experts based on case information (with all references to the polygraph tests deleted) and judicial outcomes. Those criteria failed to provide assessment of accuracy equivalent to that available in laboratory studies or confirmed criminal cases. Raskin (1978) has stated that the panel criterion is open to serious challenge because the information provided in the Barland and Raskin study was generally inadequate, agreement between the court decisions and the panel was less than perfect, and inherent bias may have existed toward judgments of innocence based on the tradition of the assumption of innocence in the absence of extremely strong evidence to the contrary. Furthermore, the number of criterion-innocent subjects was very small. As a result the 95% confidence interval for the false positives was 11%–59%, whereas the larger sample size for guilty subjects yielded a 95% confidence interval of 0%–16% for false negatives. Therefore we consider these data and those of Horvath (1977) to be of relatively low value in contrast to those presented in Table 1 and the other data described earlier that were ignored by Lykken.

Issues in the Application of Control Question Tests

Lykken (1979) stated that a sophisticated criminal might be able to augment his reactions to the control questions and "pass" the test. The only published study with such procedures used the guilty knowledge test (Lykken, 1960), which is more susceptible to false negatives than the control question test (Podlesny & Raskin, 1977) because the guilty knowledge test employs only skin resistance measures, and a truthful outcome does not require larger responses to the noncritical items, as does the control question test. The subjects were medical students, staff psychiatrists, and psychologists who were

given detailed instructions about the test structure, a strategy and methods to beat the test, and biofeedback training to control their skin resistance responses. Even with minimal consequences for being detected, the accuracy was 100%. Lykken's (1960) failure to train sophisticated subjects with little at stake to be able to beat the simpler guilty knowledge test raises extreme doubt concerning Lykken's statement, "I claim that I could train guilty suspects to successfully 'beat' the control question lie test" (p. 50). Rovner et al. (Note 1) are presently engaged in an extensive laboratory study to assess the effects of detailed information and practice on the accuracy of control question tests.

Although we are opposed for a variety of scientific and ethical reasons to the use of polygraph tests in employment situations, Lykken's opposition to the use of polygraph evidence in court is based on his lack of understanding of the control question technique, his highly selective presentation of the scientific evidence, his misinterpretations of those data that he selected for discussion, and his gross misunderstanding of the criminal justice system. The issues surrounding court use of polygraph evidence involve the level of confidence that can be placed in a truthful or deceptive outcome, the way in which such outcomes are used in the criminal justice process, and the impact of such evidence on juries.

We agree that the data indicate that false positives are more likely than false negatives, even though the rates of both types of errors are low. Even if Lykken were correct concerning the rate of false positives, for practical purposes the confidence in a truthful outcome is higher than that in a deceptive outcome, since a truthful result is more likely to be correct than is a deceptive result. The use of such findings coincides with our judicial and moral standards for acquittal and conviction. Because criminal guilt must be demonstrated beyond a reasonable doubt, considerable evidence is required for conviction, and a deceptive polygraph result is far from sufficient. In the absence of other strong evidence of guilt, no competent or ethical prose-

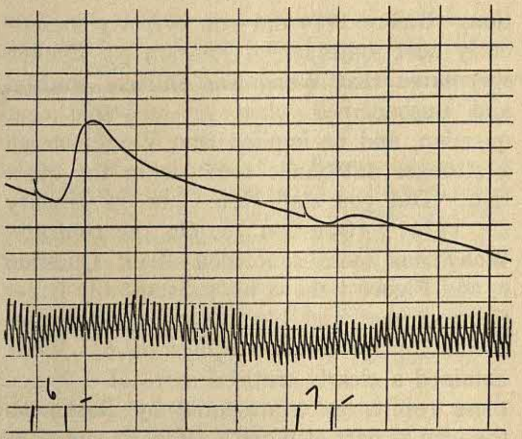

Figure 1. Skin resistance and blood pressure responses of homicide defendant William Wong to a control question (6) and a relevant question (7). The vertical marks indicate the beginning and end of the questions, and the minus sign indicates a *no* answer at that time.

cutor could or would try a case on the basis of a deceptive polygraph test. However, in the absence of overwhelming evidence to the contrary, the high degree of accuracy of a truthful polygraph result should be sufficient to cast the reasonable doubt required for dismissal or acquittal. It has become common practice for law enforcement agencies and prosecutors to dismiss charges in such situations. Given the very low accuracy of some types of evidence, such as eyewitness testimony, that are commonly used against defendants and the great weight accorded to this evidence by prosecutors and juries (Buckhout, 1974), it makes good sense to provide an opportunity for innocent suspects and defendants to clear themselves by means of a properly conducted polygraph test.

Lykken (1979) may have provided a misleading description of the William Wong case (*Proceedings at Trial,* Note 5) by failing to describe its outcome. Wong was accused of homicide on the basis of highly questionable eyewitness accounts. Wong was administered a polygraph test by Sergeant Smith of the Vancouver, Canada police department and was retested prior to his trial by Raskin. He was found to be truthful by both examiners. Using standard techniques, Raskin employed typical control questions, including the ques-

tion, "Before 1974 did you ever try to seriously hurt someone?" (Question 6). Lykken speculated that Wong was entirely truthful and unconcerned when he answered that question, and he implied that Wong showed a stronger autonomic response to the question, "Did you stab Ken Chiu on January 23, 1976?" (Question 7). On the contrary, Wong was more concerned about Question 6, and Figure 1 shows his substantially larger electrodermal and blood pressure responses to the control question (Question 6)! Wong obtained a clearly truthful score of +9, and these results were presented by Raskin to the jury as part of Wong's defense against the murder charge. It should also be mentioned that in the same court hearing, Lykken unsuccessfully opposed presenting to the jury the results of Raskin's and Sergeant Smith's polygraph tests in the defense of innocent homicide defendant William Wong. Lykken's position at the trial was in direct conflict to his previously published position that "judicious use of the polygraph in the criminal investigation context not only can improve the efficiency of police work but could also serve as a bulwark to protect the innocent from false prosecution" (Lykken, 1974, p. 738).

Lykken (1979) also claimed that the use of polygraph evidence in court would overwhelm the jury and might even be used to replace the jury system. His speculations are naive with regard to the judicial process and betray a lack of knowledge of the evidence concerning the impact of the testimony of polygraph experts on jury deliberations. As Tarlow (1975) pointed out, polygraph evidence is simply an aid to the jury in its complicated task of assessing the credibility of witnesses. As such, if the polygraph evidence has probative value, the jury is merely asked to consider it along with the other evidence in the case and to accord it whatever weight the jury finds appropriate. We have not suggested that polygraph tests should replace the jury system. In fact, the available evidence (Tarlow, 1975) indicates that juries are very cautious and that they tend to be "underwhelmed" by polygraph testimony.

Conclusion

The results of many scientific studies in laboratory and field settings as well as our published report to the U.S. Department of Justice (Raskin et al., Note 4) indicate that the accuracy and reliability of control question tests can be very high. On the basis of the present evidence, it is reasonable to conclude that the results of control question polygraph examinations conducted by competent and ethical examiners can have important and beneficial effects for the criminal justice process and for our society in general.

Notice on Author Alterations

Effective January 1979, the procedure for billing authors for alterations will change. Authors of articles in APA journals are customarily charged for alterations on proofs that result from (a) authors' errors or omissions in the manuscript and (b) changes that result from authors' failure to review the edited manuscript or the proof. Until now, alteration charges have been determined by the number of lines affected by changes requested and have been based on 1974 printing rates. Beginning with the proofs for the first issues of 1979, authors' alterations will be determined not only by the number of lines affected but also by the number of figures and pages affected and will be based on current printers' rates.

This change in alteration billing is being made so that alteration charges will more closely reflect the actual cost of changes requested and may mean larger alteration bills for some authors. Authors are reminded that alteration charges apply only when changes are made on proofs and that *there is no charge* for changes made at the manuscript stage.

Using Distance Information in the Design of Large Multidimensional Scaling Experiments

Jed Graef
University of Toronto, Toronto, Canada

Ian Spence
University of Western Ontario, London, Canada

The principal objective of this study was to discover which distances are most important in determining the recovery performance of a nonmetric multidimensional scaling algorithm. Using Monte Carlo methods we show that the large distances are critical to satisfactory performance, whereas the small and the medium distances play a much less crucial role. This finding has been reliably demonstrated across a variety of conditions, although only for a single combination of dimensionality and number of points. It turns out that certain parallels exist between this work and previous results obtained using cyclic and other incomplete designs. Finally, on the basis of these results we make some recommendations to experimenters regarding data collection procedures; these represent a simple alternative to the methods advocated by Spence and Domoney.

Good nonmetric multidimensional scaling algorithms have been available for more than a decade (Kruskal, 1964), and the large number of published applications attests to their popularity and usefulness. These procedures are capable of constructing a configuration of points in a metric space using no more than the ordinal properties of the data in a matrix of dissimilarities—thus the characterization "nonmetric." Despite the fact that a large body of experience and knowledge has been accumulated regarding the behavior of nonmetric algorithms, there have been few systematic attempts to discover which characteristics of the input data are essential for successful construction of the configuration. It is important to know the answer to this question, since in many situations it may not be feasible, or desirable, to collect all possible pairwise judgments of dissimilarity from a subject. The most obvious situation is one in which the number of stimuli is large and the resulting number of potential paired comparisons becomes too onerous a burden for even the most dedicated subject. Consequently, if some incomplete fraction of the data is to be obtained, it is essential that information be gathered regarding the distances that are most influential in determining the solution. In this article we use Monte Carlo techniques to discover which distances are most important in determining the nature of the final configuration of points and on the basis of our results suggest some possible data collection procedures for the experimenter who wishes to use a large number of stimuli.

This article is based on a paper presented at the annual meeting of the Psychometric Society, Bell Laboratories, Murray Hill, New Jersey, April 1976. This study was supported by National Research Council of Canada Grant A8531 to the second author.

Requests for reprints should be sent to Ian Spence, Department of Psychology, University of Western Ontario, London, Ontario, Canada N6A 5C2.

Method

The design of the study is straightforward and is summarized in Figure 1. A two-dimensional configuration with 31 points was generated randomly within the unit circle. Dissimilarities were simulated by computing error-perturbed interpoint distances according to two different models: multidimensional Thurstone Case V (e.g., Ramsay, 1969)—

$$d_{ij}^e = [\sum_{a=1}^{2} (x_{ia}^e - x_{ja}^e)^2]^{\frac{1}{2}}$$

with

$$x_{ia}^e = x_{ia} + N(0, \sigma_R^2); \quad (1)$$

Wagenaar and Padmos (1971)—

$$d_{ij}^e = [\sum_{a=1}^{2} (x_{ia} - x_{ja})^2]^{\frac{1}{2}} \cdot N(1, \sigma_{WP}^2), \quad (2)$$

that is, the true distance is multiplied by a random normal deviate with a mean of one. Although not invented by Ramsay (1969), for convenience we shall refer to the first model as the Ramsay model: This (noncentral χ^2) model produces an error distance whose variance increases as a function of increasing true distance, although the effect is actually quite small. For the Wagenaar–Padmos model, however, the effect is much more dramatic with the standard deviation of the error distance linearly related to the true distance. This error model is not unlike the lognormal error model that Ramsay (1977) has suggested is the most plausible for many psychological situations—the major difference being the skewness of the lognormal. The distributions are illustrated in Figure 2. The standard deviations in panel a and panel b for the Ramsay model are actually different but not by much. However, the standard deviation for panel a in the Wagenaar and Padmos model is larger than the standard deviation in panel b by exactly the same proportion as the ratio of the two true distances. These error distributions model what we feel to be the reasonable extremes that might be encountered with real data.

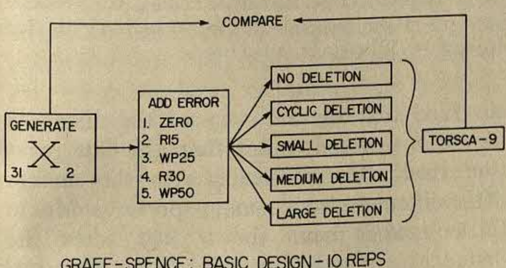

Figure 1. The design of the study. (R15 and R30 refer to the Ramsay model, with $\sigma_R = .15$ and $\sigma_R = .30$, respectively. WP25 and WP50 refer to the Wagenaar and Padmos model, with $\sigma_{WP} = .25$ and $\sigma_{WP} = .50$, respectively. REPS = replications; TORSCA = computer program used.)

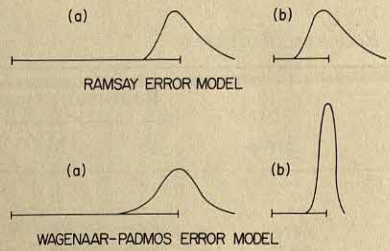

Figure 2. The two error models.

In the sequel, R15 and R30 refer to the Ramsay model with $\sigma_R = .15$ and $\sigma_R = .30$, respectively. These represent medium and high error levels and are the same as those used by Spence and Domoney (1974). For the Wagenaar and Padmos model, WP25 and WP50 refer to situations where $\sigma_{WP} = .25$ and $\sigma_{WP} = .50$, respectively. These two levels were chosen such that the variance of an average distance would be approximately equal in both error models—the appropriate relation was determined algebraically. As will be seen from the results, comparable recoveries were obtained with the two models.

The dissimilarity matrices were analyzed, using TORSCA-9 (Young, Note 1) in five ways—with no deletion, using a maximum efficiency cyclic design[1] with one-third deletion, and after deletion of the small, the medium, and the large distances (a $\frac{2}{3}$ fraction being retained in each case). Thus, for example, when the small distances were deleted, the 155 smallest of the 465 dissimilarities were discarded prior to analysis.

Results

The results for 10 replications are shown in Table 1 and Figure 3. With no deletion, we obtain the same pattern as in many previous Monte Carlo studies and note further that R15 and WP25 were about equivalent in their effects, as are R30 and WP50. This

[1] A cyclic design is a particular kind of partially balanced incomplete block design. It is not central to the substance of this paper that the reader understand how such designs are constructed and used in the multidimensional scaling context. A full and detailed description is given by Spence and Domoney (1974), and it is shown that high efficiency cyclic designs perform very well.

Note. S, M, L, and A represent the recovery statistics for small, medium, large, and all distances, respectively. R15 and R30 refer to the Ramsay model, with $\sigma_R = .15$ and $\sigma_R = .30$, respectively. WP25 and WP50 refer to the Wagenaar and Padmos model, with $\sigma_{WP} = .25$ and $\sigma_{WP} = .50$, respectively.

holds for both the root mean square (rms) correlation between true and recovered distances and for the mean absolute error; the latter is simply the average discrepancy between the generated and the recovered distances. Thus, the results seem to be independent of the error process involved. Consequently, since the two error models used are quite dissimilar, it is plausible that comparable results would be obtained using other error distributions. It should also be observed that the recovery of the distances has been assessed rather than the configuration itself. In practical terms this makes little difference, since many previous Monte Carlo studies have shown that when the distances are well recovered, so is the configuration and vice versa. For example, Spence (in press) found a correlation of .967 between recovery of the distances and recovery of the configuration.

In addition to assessing the recovery of

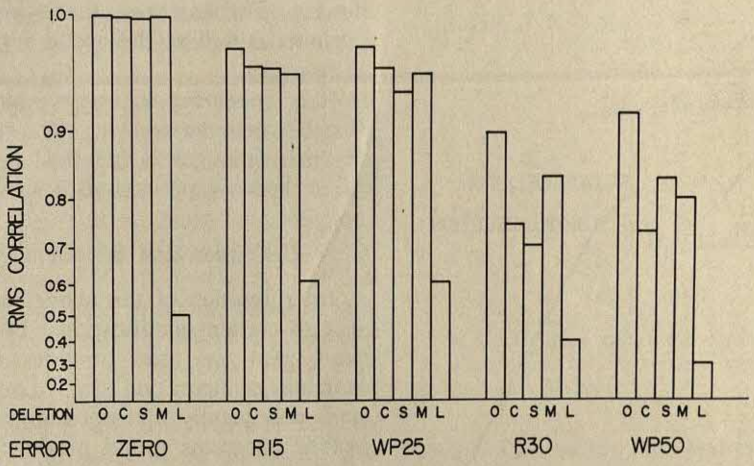

Figure 3. The recovery correlations as a function of zero (0), cyclic (C), small (S), medium (M), and large (L) deletions. (Medium and high error levels were used with both error models, as well as a no-error condition; RMS = root mean square. R15 and R30 refer to the Ramsay model, with $\sigma_R = .15$ and $\sigma_R = .30$, respectively. WP25 and WP50 refer to the Wagenaar and Padmos model, with $\sigma_{WP} = .25$ and $\sigma_{WP} = .50$, respectively.)

the total set of distances, we computed recovery statistics for the small, the medium, and the large distances. These correlations should be interpreted with some care because they are based on subsets of distances with different variances. If allowance is made for these different variances, the correlations for the small, medium, and large subsets are very close in almost all instances. The one striking exception will be discussed presently.

Cyclic deletion produced satisfactory results similar to those obtained by Spence and Domoney (1974) and Spence (in press) and warrant no further discussion. Deleting the small and medium distances produced recovery statistics very similar to the cyclic-design condition, with perhaps slightly better recovery in the high error conditions. However, when the large distances were deleted, the recovery deteriorated dramatically: Even in the zero-error condition the overall recovery was quite clearly unacceptable, and in no condition does the recovery correlation exceed .7. Tschudi (1972) has suggestd that .7 is the minimum acceptable correlation; solutions with recovery correlations smaller than this bear very little resemblance to the generated configurations. The analysis by subsets of distances shows that the large distances are the worst recovered, with some correlations negative and the best around zero. The medium and smaller distances are not as well recovered as in other deletion conditions. Obviously, a nonmetric scaling algorithm performs very poorly when it is denied information relating to the large distances.

In this study we cannot consider the incomplete fractions that were scaled to be experimental designs in the usual sense, since the missing dissimilarities are not determined a priori but are a function of the actual distances. In other words, the situation is not exactly the same as if the pattern of missing distances had been determined independent of the data, as for example, if a cyclic design had been used. Nevertheless, the end result is similar in that an incomplete matrix is scaled. Consequently, it does not seem unreasonable to refer to the pattern of retained dissimilarities as a pseudodesign. The analysis of variance (ANOVA) efficiency cannot be calculated as simply as in the case of cyclic designs (see Spence, in press; Spence & Domoney, 1974), however, it is easy to calculate the mean resistance of the pseudodesigns. This is done by considering the graph of the design to be an electrical network, with the edges of the graph corresponding to conductors of unit resistance. Johnson and Van Dyk (Note 2) have shown

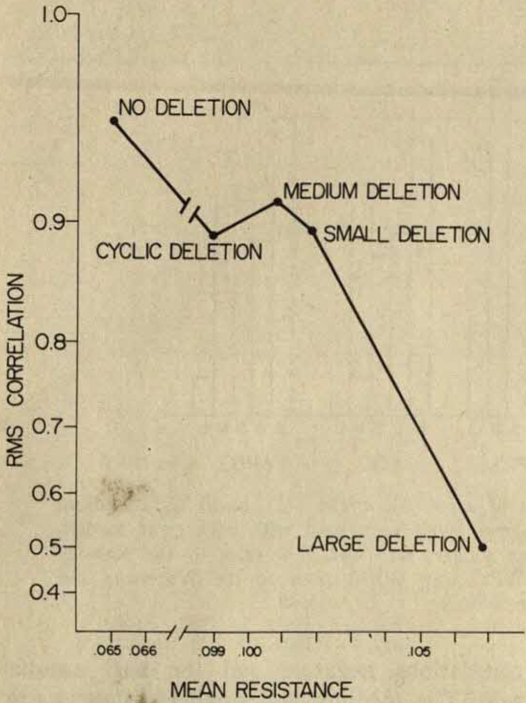

Figure 4. The recovery correlations as a function of the resistance of the pseudodesigns. (RMS = root mean square.)

that mean resistance and ANOVA efficiency are formally identical with resistance inversely proportional to efficiency. We have calculated the mean resistances for all conditions in this study, and the results are shown in Figure 4, where the recovery means are averaged over all error conditions. For the no-deletion and cyclic conditions, the mean resistance is, of course, a constant; whereas for the small-, medium-, and large-deletion conditions the values of mean resistance are the averages over the 10 replications. It can readily be seen that as mean resistance increases, the recovery correlation deteriorates. This is precisely analogous to the results of Spence (in press), where it was found that decreases in the efficiency of cyclic designs were accompanied by deteriorating recovery. It is interesting to note that deleting the large distances produces a pseudodesign with the highest mean resistance. Deletion of small or medium distances produces pseudodesigns with resistances not much higher than that of the maximum efficiency cyclic design. Furthermore, these pseudodesigns perform as well as the cyclic design in terms of recovery.

It is reassuring to observe that the relationship between recovery and resistance for the pseudodesigns is identical to that found for orthodox experimental designs.

Discussion and Recommendations

Interpretation of the above results is subject to certain qualifications. First, the program that we used provides an excellent starting configuration (see Spence, 1972), and consequently it is not known whether all scaling programs would produce comparable results. However, programs that utilize similar methods to compute the initial configuration (e.g., KYST, ALSCAL, SSA-I) should yield good results. Second, in order to conserve computer time, we did not systematically investigate configurations in higher dimensionalities, nor with larger numbers of points. Increases in the values of these parameters would have made the study extremely costly. (We did examine a few individual cases with larger numbers of points and found the same pattern of results.) Thus, extrapolation of our results is not without risk, but we are confident that with larger numbers of points there would be no change in the conclusions (cf. Spence & Domoney, 1974).

In practical terms, if an experimenter is to construct an incomplete design with the small- or medium-dissimilarity comparisons eliminated, some prior information as to the relative sizes of the dissimilarities is necessary. Such information may be obtained very easily; we suggest a number of relatively obvious methods. No doubt the reader can think of others.

1. The experimenter may rank or judge the complete set of dissimilarities. Even if this takes considerable time, the effort will usually not be deemed to be unacceptable, especially in the context of the total time and effort required to plan and set up the average experiment.

2. Pretests with actual subjects may be employed—here there is no compelling necessity for a single subject to perform the whole

task, since only approximate information is required. Several subjects may each judge a subset of the pairs.

3. Pretesting with one or more subjects using the methods of sorting may be used. Subjects will be required to group the stimuli in such a fashion as to maximize within-group similarity and minimize between-group similarity; the number of groups (k) may be fixed in advance or left to the subject but should in either case be small. One will subsequently choose not to collect dissimilarity judgments for the within-group pairs. Unfortunately, if k is much larger than three or four, this method will not yield a sufficiently large number of pairs to be discarded. The situation may be improved, to some extent, by using several judges, since their groupings will not, in general, be identical.

Independent of the strategy employed to decide which dissimilarities are to be collected, it is imperative that a sufficient number of judgments be obtained from the subject. Too few data values will not permit successful recovery. In this connection the results of Spence and Domoney (1974) and Spence (in press) should be heeded. Their results suggest that the minimum adequate fraction, F, be calculated according to the following formula:

$$F = 6m/(n - 1),$$

where m is the number of dimensions in which the scaling is done, and n is the number of points. (See Spence, in press, for the rationale.) For example, if 30 points are to be scaled in three dimensions, at least 62% of the possible pairwise judgments should be collected. As n increases, this fraction becomes smaller; however, if high dimensional solutions are required, the necessary fraction will be larger.

In conclusion, we would like to make a comment on a piece of folklore familiar to all multidimensional scalers. This is the caution against interpreting, or attaching significance to, the relative positions of points that are close together in the recovered space. In Table 1, it is seen that in the no-deletion condition the mean absolute error does not vary much over the small, medium, and large distances. This means that *relative* error in the smaller distances is much greater than in the large distances. This effect is also seen in the cyclic-, small-, and medium-deletion conditions, although not in the large-deletion condition. We have tried to illustrate the consequences of this phenomenon in Figure 5. Assuming that the error in a recovered distance is a function of the uncertainty in locating the points, it seems reasonable, given the results in Table 1, to assume that this uncertainty is about equal for all points, thus producing a constant mean absolute error in the distances. Some possible recovered locations are indicated in Figure 5 by the open and solid circles for both a small and a large true distance. These are in the same relative positions in the regions of uncertainty. It is clear that one is on much surer ground when considering the relative location of points that are far apart.

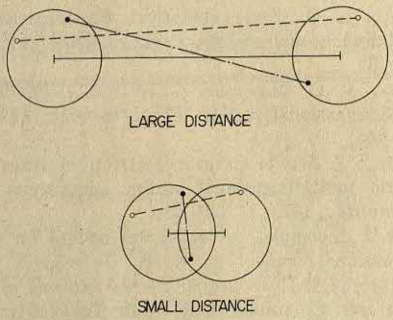

Figure 5. An illustration of the problem of attaching significance to the relative positions of points that are close together.

Toward a General Model of Small Group Productivity

Samuel Shiflett
New York University

A general model of small group performance is proposed that is designed to encompass a wide variety of models of group performance extant in the psychological literature. These existing models are shown to be special cases of the more general model proposed here, and in fact, this model is developed from a foundation of these more restricted models. In developing the general model, distinctions are made between single and multiple resources and between unique and redundant resources. The relationship between problem-solving tasks and decision-making tasks is demonstrated by means of the model. Some examples of the model's usefulness for the understanding of group processes, leadership, and social decision schemes are presented.

Research on small group performance has been moving steadily toward a stance in which performance, actual or potential, is characterized by some sort of mathematical model involving various situational and personal characteristics as input parameters. One result of this theoretical trend has been a proliferation of fairly simple models that are rather restricted in their application because of various limiting assumptions frequently involved in the development of the models. The purpose of this article is to demonstrate that a number of existing models of group performance can be thought of as special cases of a single, more general model. The development of the model begins below with the presentation of several simple models extant in the literature and then proceeds to the more complex models, all the while demonstrating that each of these currently existing models can be treated as a special case of a single, more general model. In the process, several issues relating to the creation and use of mathematical models are touched on. The article concludes with a discussion and illustration of how a mathematical model of this sort can guide the development of so-called content-oriented theories. Finally, the possible application of the proposed model to such topics as leadership, organizational structure, and group decision making is illustrated.

To begin with, three general classes of variables are proposed: *resources*, *transformers* and *outputs*. Outputs are defined as any products that can be considered as an outcome of group interaction and include objective measures of group performance but might well include more subjective measures such as job satisfaction. Resources constitute "all the relevant knowledge, abilities, skills, or tools possessed by the individual(s) who is attempting to perform a task" (Steiner, 1966, p. 274). Resources are the raw materials that are essential for the creation of the product and without which the product could not exist. Transformers constitute all the variables that have an impact on resources and determine the manner in which they are incorporated into and related to the output variables. Transformers include such variables as situational and task constraints, role systems, and certain personal characteristics that may affect the way personal task-relevant resources are utilized in the output. An input variable can be a resource in some circumstances and a transformer in others, depending on the nature of the group product and the function or purpose of the resource. For example, oratorical ability acts as a resource when the group product is a theatrical piece, but it is a transformer when

The author thanks James H. Davis, Noel Dunivant, Raymond A. Katzell, and David Meister for their valuable comments on earlier versions of this article.

the thespiantics are used during group interaction to influence the manner in which resources are incorporated into a group product not directly requiring or reflecting any theatrical resources.

This particular categorization of variables was chosen because it was both simple and adequate for the development of the general model. The system is not even particularly original; it simply groups variables within a slightly different scheme than other investigators have suggested. For examples of slight variations on this scheme, see Hackman and Morris (1975), McGrath and Altman (1966), Naylor and Dickinson (1969), and Steiner (1972).

To summarize, input and output variables have been categorized in a manner that allows the model to be stated, in it simplest form, as $P = f(T, R)$, where P represents the group output or product, T stands for transformer variables, and R represents resource variables.

In 1966, Ivan Steiner published an important theoretical article in which he outlined five basic models of small group performance, relating his models to others already existing in the literature. He subsequently wrote a book (Steiner, 1972) on small group productivity, using that article as the organizing foundation for a more elaborate consideration of group processes. The first four of Steiner's models involve a single type of resource; the fifth model represents situations requiring more than one resource for the group product. The single-resource models are discussed together as a first step in the elaboration of the general model. The multiresource model is then considered as a somewhat more complex level of the general model.

Single-Resource Models

Steiner's (1966) *additive model* describes situations in which the task demands require every member of a group to perform the same function in a manner that causes the members' resources to enter the potential group product in a simple, additive manner. Under these conditions, average potential group productivity will vary as a positive, linear function of group size. The *disjunctive model* describes a situation in which the potential productivity of a group is determined entirely by the resources of its most competent member. The *conjunctive model* describes tasks in which potential productivity is restricted to a level that is established by the group's least competent member. The *compensatory model* describes a situation in which biases or errors in individual resources or products, such as judgments, are normally distributed and thus tend to cancel themselves or compensate among themselves and the group product is essentially an average of all the members' resources.

It is possible to demonstrate that all of Steiner's models can be treated as special cases of a more general model, which can be written as

$$P = \sum_{i=1}^{n} T_i R_i, \tag{1}$$

where P represents (actual) group productivity, R is the task-relevant resource of the ith person, and T is a weight representing the sum total of all constraints operating on the utilization of resources. In the case of Steiner's additive model for predicting potential productivity, T has the same value for all individuals in the group and can be written

$$\hat{P} = nT\bar{R}, \tag{2}$$

where P represents potential productivity, $\bar{R}$ represents the average ability of each group member, and n is the group size. It should be noted that the formula for *actual productivity* (P), strictly following Steiner's model, would be

$$P = \textit{potential productivity} - \textit{motivation and coordination losses.}$$

However, in the present case, motivation and coordination losses are considered to be a part of T acting on R in a multiplicative manner. Thus, T can be thought of as a function of task constraints, motivation losses, coordination losses, and in fact, any other variable that impinges on group resources in such a way as to change potential productivity from the ideal case expressed in Equation 1, when $T = 1$.

With the additive model now in hand, it is a simple matter to show that both the disjunctive and conjunctive models are also special cases of the general model, in which group members are thought of as constituting an

ordered set of individuals. To show this, Equation 1 can be rewritten to reflect the rank ordering of members from least capable to most capable, as follows:

$$P = T_L R_L + T_{L+1} R_{L+1} + \cdots + T_{M-1} R_{M-1} + T_M R_M. \quad (3)$$

Here, L represents the least capable member and M represents the most capable member. When task and situational constraints are such that only the best member's performance determines productivity, that is, if task constraints are disjunctive, then $T_M > 0$, all other $T = 0$, and the disjunctive model is characterized by the equation,

$$P = T_M R_M. \quad (4)$$

Note that T_M is not necessarily equal to 1, since other constraints can still moderate the extent to which resources become products. However, T_M is the only transformation weight greater than 0. As was pointed out by Steiner (1966) and Davis (1969), this model is essentially the same as Lorge and Solomon's (1955) "Model A," Thomas and Fink's (1961) "rational model," and the model proposed by Taylor (1955). Also closely related is Steiner and Rajaratnam's (1961) method for predicting group competence levels.

In a similar fashion, when task and other situational constraints are conjunctive in nature, $T_L > 0$, and all other $T = 0$, resulting in the conjunctive model,

$$P = T_L R_L. \quad (5)$$

The compensatory model can similarly be expressed in terms of the general Equation 1 if T_i takes the value C_i/n, where n is the group size and C_i represents the impact of all other constraining variables, including the distribution of errors. In fact, any averaging model is a transformation of the general additive model in which T has been appropriately adjusted for the group size.

Steiner (1972) subsequently introduced the concept of a *discretionary task* to describe conditions in which the group members can combine their individual resources in any manner they wish. This is another way of saying that all four models described above are special cases of the general model except that, for Steiner, a discretionary task implies that group members themselves are able to determine what values T takes instead of the values being imposed by situational characteristics not under group control. Similar points have been made by Hackman and Morris (1975) and Shiflett (1972).

Multiple-Resource Models

Steiner's (1966) final category of task types, the complementary tasks, are designed to deal with cases in which a single individual performs only a part of the total task while other group members, possessing different kinds of resources, perform the remaining parts. Steiner further subdivided complementary tasks into those with *unshared resources* and those with *partially shared resources*. Steiner originally argued that to be complementary the task must be divisible into subtasks and that the resources required for the various subtasks must differ in a qualitative manner. Subsequently, Steiner (1972) emphasized the divisibility requirement by referring to these types of tasks as *divisible tasks* and stressed the idea of appropriately matching resources to the requirements of the various subtasks. Laughlin and Branch (1972) suggested that although this strategy can be referred to as a division of labor, it can also be reasonably seen as a division of resources. Thus, in order to optimize or maximize group performance, the division of resources must be coordinated with the partitioning of the task, whether accomplished by the group itself or by a superordinate organization.

Under these conditions the distinction between shared and unshared resources disappears, since by appropriate assignment of individuals to subtasks, resources may be redistributed so that they are not shared on any subtasks even though they are shared within the group as a whole. For this reason, the unshared resources model can be treated as a special case of the more general shared resources model. Similarly, it is possible to demonstrate that all the single-resource models are special cases of the unshared resources model, which, as we have just shown, is a special case of the shared resources model.

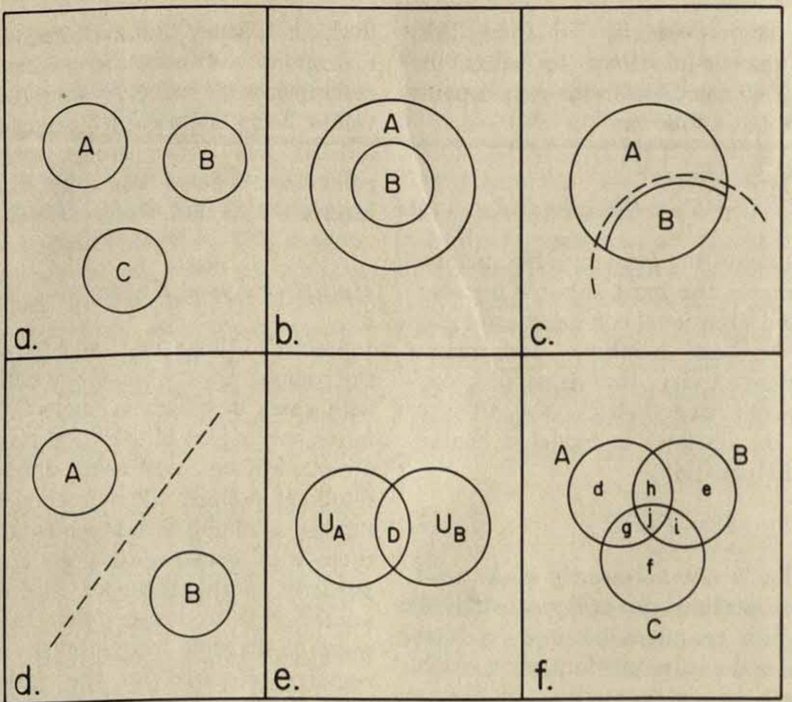

Figure 1. Venn diagrams illustrating various distributions of resources within a group.

To illustrate these propositions, set theory operations can be utilized to describe a series of identities. The general model, expressed in Equation 1, can now be redefined as the union ($\bigcup$) of all members' resources available for the group product:

$$P = T_1R_1 \bigcup T_2R_2 \bigcup \cdots \bigcup T_{n-1}R_{n-1} \bigcup T_nR_n. \quad (6)$$

T_i acts as a constraint on R_i, changing it from the total amount potentially available from the group member into the amount actually available as a result of various task and situational conditions. Proceeding as before, we can now redefine the four basic models already described.

The additive case exists when

$$T_1R_1 \bigcup T_2R_2 \bigcup \cdots \bigcup T_nR_n = R_1R_1 + T_2R_2 + \cdots + T_nR_n = \sum_{i=1}^{n} T_iR_i. \quad (7)$$

This situation can be illustrated by the use of Venn diagrams, as in Figure 1a, and is the case defined by Equation 1. That is, in terms of Figure 1a, the additive case exists when $A \bigcup B \bigcup C = A + B + C$.

The disjunctive case exists when

$$T_1R_1 \bigcup T_2R_2 \bigcup \cdots \bigcup T_nR_n = T_MR_M. \quad (8)$$

Here, $T_M > 0$, and all other $T = 0$. The conjunctive case exists when

$$T_1R_1 \bigcup T_2R_2 \bigcup \cdots \bigcup T_nR_n = T_LR_L. \quad (9)$$

In this case, $T_L > 0$, and all other $T = 0$.

It should be evident that in keeping with the assertion that all three models are special cases of the more general model, the left side of the three expressions does not change, for it *is* the general model.

The disjunctive and conjunctive cases can occur in several different ways, which are illustrated in Figures 1b, 1c, and 1d. In Figure 1b, the resources of the least able member (B) are completely encompassed by those of the

most able member (A). This overlapping of resources is sometimes referred to as redundancy. In this situation, if no other constraints exist, then Member B is unable to add anything more to the product than what Member A already has the potential to contribute. In other words, the disjunctive case exists and $A \cup B = A$. On the other hand, if some constraint exists so that the appropriate combination rule is $A \cup B = B$, then the conjunctive case exists. This situation is illustrated in Figure 1c, where the dashed line symbolizes a constraint preventing the use of A's superior resources.

In Figure 1d, resources are not shared, in contrast with the shared resources situation of Figures 1b and 1c. The dashed line again represents external constraints that operate in a manner that prevents one member from utilizing his or her resources or in which productivity is totally dependent on one member. If productivity is determined by the most able member, then this particular situation is disjunctive, but if productivity is totally dependent on the least able member, then the situation is conjunctive. It should also be evident that the additive model (Equations 1 and 7 and Figure 1a) is equivalent to the unshared resources model, whether or not the resources are qualitatively similar.

Compensatory situations can exist in a variety of ways, but it can be said that a compensatory model is appropriate when the various constraints on resources operate in such a way that the following identity is true:

$$R_1 \cup R_2 \cup \cdots \cup R_{n-1} \cup R_n = \left(\sum_{i=1}^{n} R_i\right)/n. \quad (10)$$

The Model in Terms of Matrix Operations

Resources within a group can be thought of as being arrayed in a resource matrix, **R**, in which rows are defined by group members (m), and columns are defined by a discrete, mutually exclusive form of resource (a),

$$\mathbf{R} = \begin{array}{c} \\ m_1 \\ m_2 \\ \\ m_i \end{array} \!\!\begin{array}{c} \begin{array}{cccc} a_1 & a_2 & \cdots & a_j \end{array} \\ \begin{bmatrix} r_{11} & r_{12} & & r_{1n} \\ r_{21} & & & \\ & & & \\ r_{m1} & r_{m2} & & r_{mn} \end{bmatrix} \end{array}. \quad (11)$$

Entries consist of the amount of each resource (r) provided by each member. In a single-resource situation the matrix would be a column vector. In all cases, resources are assumed to be directly relevant and necessary for creating the group product, whatever it is defined to be. Thus the nature of this matrix will vary widely depending on the nature of the group product. Often, each column will represent a qualitatively different resource.

These different resources must be combined in some fashion to finally represent a group product. This combination rule usually involves rescaling the resources for proper reflection in the product, but it also requires specification of a particular rule. Although this task is formidable, several approaches to the problem have been suggested. Job analysis (Zedeck & Blood, 1974) and synthetic validity (Guion, 1965) represent approaches to breaking products (or their antecedent tasks) into the subsets of skills and resources required to accomplish the task. The entries can vary in nature from interval measures of skills and abilities to probabilities ranging from 0 to 1 of a certain response being in an individual's behavioral repertoire.

Implicitly or explicitly, all theories of group performance specify one or more rules for the manipulation of the resource matrix. The rules are specified in a transformation matrix, **T**. In the additive model, **T** is a vector in which all entries take on the same value; **R** is also a single vector, indicating the amount of the resource provided by each member. The conjunctive and disjunctive models specify a **T** vector containing all entries equal to 0 except for the one entry specific to either the most or least able member.

As the product and the model become more complex, so do the matrices representing the model. In particular, the transformation matrix may be the final representation of a whole series of matrix operations representing some model of group process. An example of this explicit use of matrix operations to represent group processes is structural role theory (Oeser & Harary, 1962, 1964; Oeser & O'Brien, 1967). The basic elements in the model consist of persons, positions, tasks, and the various directional relationships among these elements. These elements are then com-

bined in a series of mathematical operations that result in a specific index describing some aspect of the situation. The particular operations are a function of the index of interest, but the elements are always those listed above. Elaborating on the basic model, O'Brien and his associates have developed indexes of collaboration requirements, cooperation requirements, certain task characteristics, and potential leader influence (O'Brien, 1968, 1969a, 1969b; O'Brien, Biglan, & Penna, 1972; O'Brien & Owens, 1969; Witz & O'Brien, 1971). Basically, then, structural role theory can be thought of as one approach to specifying the transformation matrix, **T**.

Unique Versus Redundant Resources

We have already noted the fact that resources can be distributed within a group and applied to the group product in a variety of ways. Continuing the use of set notation, resources are characterized below as either duplicated (redundant) or unique. If two individuals' resources are characterized by the Venn diagram illustrated in Figure 1e, then the following sets can be defined: A = Member A's total resources; B = Member B's total resources; U_A = A's unique resources, those not possessed by B; U_B = B's unique resources; and D = redundant or overlapping resources possessed by both A and B. From these definitions the following sets can be further identified: $A \supseteq (U_A \cup D)$; $B \supseteq (U_B \cup D)$; $U \supseteq (U_A \cup U_B)$.

As a matter of fact, a total set of resources can be characterized in any number of ways, depending on the requirements of the particular model or theory being espoused. For example, some models of performance have emphasized the amount of unique resources available, sometimes referred to as the pooling of resources, as in the case of Kelley and Thibaut (1969) and that of the research by Laughlin and his associates (Laughlin & Branch, 1972; Laughlin, Branch, & Johnson, 1969; Laughlin & Johnson, 1966). Other models have emphasized the impact of the amount of redundancy, or overlap, on performance, for example, Zajonc and Smoke (1959) and Shiflett (1972, 1973, 1976).

The number of sets of overlapping data increases rapidly as group size increases. In groups of size two, there is one set of shared resources. In groups of size three, there are four sets of overlapping resources, including the set that is common to all three members. This situation is illustrated in Figure 1f, and the sets are labeled g, h, i, and j. When $N = 4$, *common resource sets* = 11, and when $N = 5$, *common resource sets* = 25. Obviously, this approach to the subdivision of resources rapidly becomes unwieldy as group size increases, but it does illustrate the fact that the set of available resources can be broken into subsets, using any number of different criteria. And though the number of sets can quickly burgeon into an unmanageable size as group size increases, in practice this is unlikely to represent a major problem, since simplifying procedures and assumptions can be applied that substantially reduce the number of sets that would have to be dealt with. For example, it seems likely that many of the subsets of shared resources will be trivially small or nearly identical to other subsets, so resources could be regrouped into more manageable and possibly more meaningful sets.

The distinction between unique resources and shared resources provides several interesting implications for the manner in which individual resources will be utilized in the group product when the resources consist of sets of discrete units of the resource and when the task is subdivisible. For example, it should now be apparent that the fact that two or more individuals possess the same resource does not increase the total set of available resources but does increase the probability of that resource being used. Recognizing that some resources are shared provides one explanation for the frequent finding that groups are less productive than would be expected by a knowledge of each individual's resource score. In other words, this distinction permits the recognition of the fact that $(A \cup B) \leq (A + B)$.

Although the two sets of variables, unique and redundant, are potentially independent of each other, in most cases they probably are not. They must always be considered together in looking at group performance, even if one or the other turns out to be an empty set.

Failure to consider both sets adequately can lead to inadvertent confounding of one with the other. For example, in the series reported by Laughlin and his associates (Laughlin & Branch, 1972; Laughlin et al., 1969; Laughlin & Johnson, 1966), subjects of varying degrees of ability (resources) were composed into 2-, 3-, or 4-person groups in factorial combinations of member ability. The basic purpose of the studies was to test Steiner's (1966) complementary model, which in this context asserts that groups with members having nonredundant (unique) resources will do better than groups with all members having the same (redundant) resources, assuming that all resources are relevant to the task product.

The presence and amount of unique resources in a group were inferred by Laughlin and his associates by looking at the difference in ability levels of the group members. Thus, a member of low ability was predicted to be unable to contribute any new resources to those of a member of high ability, and productivity would be determined entirely by the most able member's resources, that is, using the present notation, $P = U_M + D$. In the case of equal ability, however, it was assumed that both provided some unique resources (i.e., $U_A > 0$ and $U_B > 0$) in addition to a core of overlapping resources, D. Thus, in this particular case, P was assumed to equal $U_A + U_B + D$ and was predicted to be greater than when either member worked alone or with a member of lesser ability.

The data appeared to support these predictions strongly. However, there are several problems in the design and interpretation of these studies. In the case of members of unequal ability, we notice that although the complementary model does indeed imply the prediction that $P = U_M + D$, so does the simpler disjunctive model. As was illustrated at the beginning of this section, any member's abilities can be thought of as containing the subsets U and D. Thus the most able member's abilities, R_M, are composed of unique resources, U_M, as well as those shared by other members, D, or $R_M = U_M + D$. By simple substitution we see that the prediction of the complementary model, $P = U_M + D$, is identical to that of the disjunctive model, $P = R_M$.

A more important problem in the Laughlin series consists in the definition of unique and redundant resources. The amount of unique or pooled resources is clearly varying systematically as a function of variations in the ability level of group members, as was asserted by the researchers; however, the amount of redundancy is also varying systematically, and the precise relationship of one set to the other cannot be determined from the data. Thus, it is not possible to state unequivocally that uniqueness of resources determined the results, since redundancy could equally have been the cause. Or more likely, some combination of the two sets explains the results. In order to partition these effects, empirical measurements of both redundancy and uniqueness of resources must be made.

The difficulty in assessing redundancy in most small group research can be illustrated by looking at two individuals who each score 50 on a 100-item vocabulary test. How much redundancy is represented in the two scores of 50? If each person answered 50 items correctly we could argue that there is 100% redundancy. However, this condition would hold only if both members correctly answered exactly the same items. If all the items are of equal difficulty, then redundancy could range from 0% to 100% in the case of 50 of 100 items. It should be obvious, then, that it is not possible to infer directly the amount of redundancy from ability levels alone, although we would expect that as one member's ability becomes increasingly greater than another's, $A \cap B \rightarrow A$.

Much of the decision-making research avoids this problem because it is possible to precisely specify the redundancy term by causing it to be a characteristic of the environment (the **T** matrix) rather than the resource matrix (Slovic & Lichtenstein, 1971). Shiflett (1972, 1973, 1976) was also able to manipulate redundancy by arbitrarily dividing the task in several ways, thus making redundancy a function of **T** instead of **R**. However, he was not any more able to estimate the actual amount of redundancy present in the shared-labor work strategy than were Laughlin and his associates in their shared-labor task.

The general model, written to reflect the distinction between shared and unique re-

sources, is

$$P = \sum_{i=1}^{n} T_i U_i + \sum_{i=1}^{n} T_i^* D, \qquad (12)$$

where U_i represents the unique resources of Individual i, T_i is the transform weight reflecting the utilization of those resources in the group product P, and T_i^* is the transform weight applied to redundant resources, D. T and T^* may differ depending on the particular constraints operating in a group. It might seem that T^* should be constant across all individuals, since D is defined to be, but again, particular constraints operating in a group situation may cause this not to be so. That is, some people's common resources are more likely to be used than are those of others.

Discussion

To illustrate how the proposed model might be used, two examples of translation from mathematical abstractions to psychological realities are presented below. The first illustration comes from the area of leadership, the second considers some current approaches to decision making.

Leadership

In terms of the present model, leadership may be defined as a *resource recognition* or a T-*facilitating* function. That is, leaders must recognize the existence of resources available to them through their group members, and they must be able to do so to the extent that they can locate those resources with enough precision that they can then take appropriate actions to facilitate their effective inclusion in the group product. Facilitative behaviors may include a wide variety of actions, from restructuring an organization in order to better utilize the existing distribution of resources to soothing angry feelings and increasing the motivation and morale of the group so that the members are willing to apply their resources to the task. Thus a leader's appropriate or most effective behavior can vary drastically, depending on the situational requirements, but in every case the behavior should have the same end result: to maximize P by making appropriate adjustments to the T weights over which she or he has some conscious control.

It would seem that the approach to leadership suggested here fits rather nicely with the ideas recently proposed by Graen and his associates (Dansereau, Cashman, & Graen, 1973; Graen, 1976). They suggested that the appropriate unit of analysis for examining leadership processes is the "vertical dyad," consisting of the superior and only one subordinate of the several in a work unit. In this approach the vertical dyad reflects the role relationship linking each group member and his or her superior. To the extent that this process link affects an individual's contribution to the group product it is represented in the model by T. Each vertical dyad can be represented by a single number reflecting "influence," and the set of all vertical dyads in a work unit can then be written as a vector **T**, containing a series of *t*s, one for each group member or vertical dyad. It will be recalled that we pointed out that the **T** matrix is the culmination of what might be a whole series of preliminary matrix operations reflecting various aspects of the situation. What has traditionally been called *leadership style* is then simply a description of the various components of the summary transformation index that the leader actually influences in his or her attempts to increase performance.

The effectiveness of any leadership style is a function of the context within which the style is exercised. In some situations it would be more appropriate to emphasize organizational factors, whereas in others it would be more appropriate to influence motivational factors. Obviously, a good leader is one who emphasizes the right components at the right time. A flexible leader is one who can change emphasis or style as situational requirements change. This approach also allows us to see a common ground uniting Graen's approach with Likert's (1958) idea that leadership is an adaptive process and Naylor and Dickinson's (1969) idea that a group's communication structure, which includes leader communication, is dependent on task structure and work structure.

Vroom and Yetton (1973) proposed a model of leadership as a decision-making process that also appears to be related to the approach being

proposed here. They suggested that a leader has a series of discrete, alternative behavioral processes that can be used in a problem-solving situation. The alternatives can range from behaviors that could be labeled "autocratic" through those called "participative." The leader must make a series of sequential decisions in evaluating each situation in order to determine the most appropriate behavior for that situation. Thus, their model stresses the need for behavioral differences on the part of the leader over situations. This same implication is a keynote of the vertical-dyad approach of Graen and his colleagues and is a direct implication of the present model.

It is noteworthy that the effect of a participative style of leadership is effectively to assign an equal weight to all members' resources, whereas the autocratic style is characterized at its extreme as one with a matrix of group members' weights equal to 0 and a leader weight equal to 1.

Vroom and his associates noted that maximizing group efficiency or productivity is not always the only criterion for determining a behavioral style. Other considerations, such as humanistic concerns or quality of interaction or a pragmatic desire to develop certain social characteristics of the members might also influence the particular leader style. The latter decision base was termed Model B by Vroom and Yetton (1973), and the decision model involving only group productivity was termed Model A. Using the rationale of the present model it appears that Model A is in fact a subset or special case of the more general Model B. By defining group productivity, P, as the set of all possible outcomes and products resulting from group processes, then P is a set containing not only traditionally defined group performance criteria but also group-level perceptions such as morale or group atmosphere and individual-level perceptions, attitudes, and characteristics such as job satisfaction and feelings of acceptance, worthwhile accomplishment, or personal growth. To each of these elements in the product set a weight reflecting something like importance or relevance can be attached forming a vector, $\mathbf{I}$, with elements equal in number to those contained in the $\mathbf{P}$ vector. These importance or relevance weights contained in the $\mathbf{I}$ vector are frequently, but not always, determined by some authority external to the group or by the leader of the group. Thus the president of a production firm may determine that the only relevant product from an assembly line is the physical product being assembled and nothing else. In this case, a relevance weight of 1 is attached to the group product and weights of 0 are attached to all other nonmaterial group outcomes, resulting in an extreme example of Model A. Obviously, there is no reasonable case in which all potential outcomes can be simultaneously considered, but any case in which one or more nonmaterial outcomes are given weights greater than 0 can be considered to be a variation of Model B. Variants of Model B can be defined by the appropriate importance vector. Thus sensitivity, therapy, or team-building groups would usually be characterized by a vector containing weights of 0 for material group products but large weights for personal or interpersonal characteristics deemed important to the group.

Decision-Making Tasks

In a previous section it was suggested that one useful way of conceptualizing the resource matrix was in terms of its redundancy. A summary vector of redundancy could consist of a row of entries, each of which indicates how many members have a particular resource. Thus the vector would contain as many entries as there are defined resources. Using this concept it is possible to demonstrate a close relationship between problem-solving or general performance tasks and decision-making tasks. I am suggesting that many decision tasks require as their basic matrix the redundancy vector, whereas problem-solving tasks require the summary resource matrix or some combination of the resource and redundancy matrices. The reason for this distinction is found in the distinctly different way in which resources are incorporated into the group product in the two types of tasks. Resources (or response alternatives) in a decision task are mutually exclusive, and the use of one response alternative precludes the use of the remaining response alternatives. That is, if my response alternatives are *yes* and

no, I cannot use both responses at the same time. If I try to, I really have not made a decision. In a problem-solving task, on the other hand, resources can be combinatorial so that the use of one resource does not preclude the use of additional resources but actually supplements or combines with other resources to reflect the final product.

Pursuing the special characteristics of decision tasks, we find that there is typically a clearly defined set of response alternatives, which is frequently quite limited in scope, often consisting of only two or three alternatives. Because of this fact and because the response alternatives are mutually exclusive, it is convenient to think of each response alternative as a qualitatively distinct resource. Thus, a two-alternative decision task is defined as requiring two resources, a three-alternative decision task has three resources, and so forth. Under these circumstances, the concept of redundancy takes on special importance. By definition, each member has only one resource (response alternative). Thus it is not possible for subjects to have multiple resources. Because response alternatives are always mutually exclusive within a group member, the **R** matrix has the characteristic that each subject vector contains entries consisting of $r - 1$ 0s and a single 1, for example,

$$\mathbf{R} = \begin{array}{c} \\ S_1 \\ S_2 \\ S_3 \\ S_4 \end{array} \begin{array}{c} \begin{array}{ccc} A_1 & A_2 & A_3 \end{array} \\ \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{bmatrix} \end{array}.$$

This characteristic simply is reflecting the fact that when one response is made, the other cannot occur. The redundancy matrix, **D**, is then the simple sum of resources across subjects; using the same example as above,

$$\mathbf{D} = \begin{array}{c} \begin{array}{ccc} A_1 & A_2 & A_3 \end{array} \\ \begin{bmatrix} 2 & 1 & 1 \end{bmatrix} \end{array}.$$

Because of the way decisions are typically made, it is the redundancy vector that is the primary resource matrix of interest in this type of task. Transformation rules (**T** matrix) thus operate on the **D** matrix of redundancy rather than on the original resource matrix, **R**.

Recently, Davis (1973), in an important theoretical article, proposed a model for describing the nature of the social processes leading to a group decision that is a perfect illustration of this conceptualization of resources. His theory assumes that, as suggested above, response alternatives defined by the decision task are mutually exclusive and exhaustive. An individual probability distribution is assumed to exist that characterizes the population from which a decision-making group is formed. Randomly formed groups from such a population display an internal distribution of preferences that Davis called a "distinguishable distribution" and that is identical to the redundancy vector in the present model. To quote the succinct summary statement by Davis, Kerr, Sussman, and Rissman (1974), "In this system, response alternatives, but not particular people, are considered distinguishable" (p. 250). In the Davis model the population's individual probability distribution (the population redundancy vector) is operated on by a "social decision scheme" matrix to yield an estimate of the probability of a group deciding for each alternative. The social decision scheme matrix is a mathematical statement describing how each possible group-preference distribution is resolved through social interaction, and as such, is equivalent to the presently defined transformation matrix, **T**.

Davis's (1973) approach can be seen as a special treatment of unique and redundant resources in which the social decision scheme determines or influences the relative importance of the unique and redundant resources. In this scheme, a shared resource is any resource that has more than one adherent in the group, and a unique resource is one that has only one proponent. Thus, with respect to the set of response alternatives, $A_1, A_2 \cdots A_n$, and occupancy numbers (redundancy), $r_1, r_2 \cdots r_n$, it can be said that when $r_n = 1$ for any A_n, that set is a nonredundant or unique set. And when $r_n > 1$ for any A_n, then the set is a redundant set.

The impact of redundancy on the final outcome will be determined by the social decision scheme operating on the resources. Some of the social decision schemes have been given psychologically descriptive titles by Davis, examples of which are "majority, equiprobability, plurality, proportionality, and

truth-wins." These matrices can represent very formally presented rules that are agreed on by the group, or more subtle and unarticulated influences such as cultural mores, or even task characteristics.

Conclusion

A number of factors have been shown to influence the relative contribution of resources (R) to the group product (P). In addition, many factors potentially enter into the system of formulas for estimating T. In fact, the system is usually so overdetermined that unique solutions seldom exist. Any number of different combinations of group-task or transformational factors can result in essentially the same **T** matrix. Thus a host of influences might affect a group, both internally and externally, and yet the group can still make adjustments so that little change in actual productivity occurs. However, many important constraints on the resource–product relationship are often not amenable to change. Under these conditions many factors used for estimating T have the status of constants and the system rapidly moves from its overdetermined status to one in which there are few solutions. Any attempts to improve or change group performance by affecting the **T** matrix are severely handicapped under these conditions. A simple example illustrating this situation would be a routinized assembly line in which all operations are highly determined and possible variations in operating procedures are severely limited.

Of course, in some cases neither the **T** nor the **R** matrix can be substantially changed without incurring great costs. The assembly line again serves as an example. Once workers have been adequately trained, the resource matrix has reached a maximum—There is no way to increase resources within the constraints of the assembly line. To the extent that changing the assembly line itself (i.e., the **T** matrix) involves extensive retooling of expensive machinery, neither matrix is likely to be changed unless other considerations that are unrelated to the **R** or **T** matrix, such as social or humanitarian concerns, are brought to bear on the decision to change the situation.

The extent to which the present model will adequately characterize a group's resource–transform–product system is partially dependent on the time frame within which the model is to characterize the group. In general, the longer the time interval, the more opportunity there is for unexpected perturbations in the environment to occur and thus for the model to be inadequate. For example, the amount and distribution of resources within the group do not have to remain constant. Thus the amount of resources available within the group can change drastically over a very short period simply as a result of the transformation processes within the group. A group can start with each member bringing unique resources to the task at hand; that is, task-relevant redundancy equals 0. But as a result of group interaction, not only has a product been created that presumably reflects the various resources but the group members may have distributed duplicate resource sets among themselves. Task-relevant redundancy now approaches 100% as a result of learning. When this occurs, the resource matrix changes substantially, and this in turn may affect the adequacy of the existing **T** matrix.

As the group interacts over time, interim products occur both in terms of the current status of the formal group product and in terms of interpersonal relations and individual perceptions. These interim outputs are frequently continuous in nature, but by arbitrarily dividing the group interval into small time units, a series of interim products can be identified as the group progresses toward its final goal. These interim product states act as inputs to the next time frame, influencing the manner in which member resources can be incorporated into the group product. If, for example, performance on a subtask changes the nature of the resources available for the remaining portion of a task, the final group product can also be expected to differ from what might be expected from a knowledge of the resources available at the beginning of the task interval. The Lorge and Solomon (1955) Model B is an early attempt to incorporate this fact of life into a mathematical model. Restle and Davis (1962) and Davis and Restle (1963) inferred group-performance characteristics over time as a function of the number

of distinct, sequential subtasks within a group task. Recently, Davis (1973) presented an interesting analysis of the potential effect of sequential decision making on interim resource matrices as a decision-making task moves up an organizational hierarchy.

The model proposed here attempts to demonstrate that a number of existing models of group performance can be seen as existing within a single, unified conceptual framework that still retains a fair degree of simplicity. In fact, given the present framework, it is possible to see that most of the models in the literature are really only special cases of this model, in which a specific pattern of T weights is postulated to have a specific effect on group resources (R). This approach has often taken the form of comparing two or more T patterns (e.g., conjunctive vs. disjunctive, or equiprobability vs. majority rule vs. truth-wins). In some cases the **R** matrix is the primary focus. Only rarely does one come across careful consideration of both the **T** matrix and the **R** matrix in the same study. Unfortunately, these cases are restricted almost entirely to the decision-making literature (e.g. Davis, 1973; Slovic & Lichtenstein, 1971).

It should be kept in mind that the present model can be thought of as a representational framework, incorporating a variety of smaller models. As such, in its current form it has only limited capability for generating precisely formulated predictions. In other words, the model does not represent a new theory of group productivity, nor does it solve the very real problems of assessing resource and transformation variables or of determining the best fit between the **T** and **R** matrices. Research along all of these fronts is in progress and appears to be making slow but steady advances. Hackman and Morris (1975) presented an excellent review and discussion of many of these practical problems. I hope that the approach presented here, by illustrating the need to consider the transformation and resource variables simultaneously and by illustrating the underlying similarities among a variety of existing models, will provide a general framework within which these other issues can be more clearly defined and resolved.

Research incorporating both transformation and resource variables is growing and has, I believe, an exciting future. Questions about, for example, the ideal T weights for a given resource set are now being asked, as well as broader questions regarding the effects of various patterns of T weights where characteristics of the **R** matrix are not entirely known. Since ideal weighting is often impossible because of lack of information or other systematic distortions in weighting due to group processes (Steiner, 1972), research is necessary to determine ways of minimizing bias or to determine the effects of various conditions on probable weightings. One method of attacking this problem has been to compare the effectiveness of various formally defined weighting schemes on group judgments. The research program of Davis (1973) and his associates illustrates this approach. Other recent research has demonstrated that an averaging or equal-weighting model outpredicts differential-weighting models in a variety of conditions and may be especially effective when the **R** matrix is not known (Einhorn, Hogarth, & Klempner, 1977). A different but related approach would be to determine the optimal distribution of resources for a fixed **T** matrix. The approach would be applicable to situations in which there is little freedom to vary the surrounding environment.

All of these approaches, with their different methods, terms, and focuses, are attempts to capture a general process by which individual resources are transformed into a group product through group processes. The present framework represents an early step toward bringing together these diverse models into a unified approach to the study of small groups, by concentrating on the similarities among these models. It is hoped that in doing so, future research will begin to come together into more meaningful patterns and that the current state of affairs in the study of group dynamics, in which theoretical integration is almost nonexistent (Shaw, 1976), will begin to move toward a state of genuine integration.

Comparative Effectiveness of Paraprofessional and Professional Helpers

Joseph A. Durlak
Southern Illinois University at Carbondale

Forty-two studies comparing the effectiveness of professional and paraprofessional helpers are reviewed with respect to outcome and adequacy of design. Although studies have been limited to examining helpers functioning in narrowly defined clinical roles with specific client populations, findings have been consistent and provocative. Paraprofessionals achieve clinical outcomes equal to or significantly better than those obtained by professionals. In terms of measurable outcome, professionals may not possess demonstrably superior clinical skills when compared with paraprofessionals. Moreover, professional mental health education, training, and experience do not appear to be necessary prerequisites for an effective helping person. The strongest support for paraprofessionals has come from programs directed at the modification of college students' and adults' specific target problems and, to a lesser extent, from group and individual therapy programs for non-middle-class adults. Unfortunately, there is little information on the factors that account for paraprofessionals' effectiveness. Future studies need to define, isolate, and evaluate the primary treatment ingredients of paraprofessional helping programs in an attempt to determine the nature of the paraprofessional's therapeutic influence.

Evaluations of research involving paraprofessional therapists have been highly positive. Reviewers concentrating on the use of college students (Gruver, 1971), community volunteers (Siegel, 1973), and parents (Berkowitz & Graziano, 1972; Johnson & Katz, 1973; O'Dell, 1974) or discussing paraprofessional therapy outcome research in general (Karlsruher, 1974) have agreed that relatively untrained workers can make a significant service contribution within the mental health field. Conspicuously ignored, however, has been the research comparing the relative effectiveness of paraprofessionals and professionals. This article attempts to review and evaluate this comparative research with respect to outcome and adequacy of design.

A broad range of helping roles is considered. Studies selected for review include individual and group psychotherapy, crisis counseling, behavior modification, social and vocational rehabilitation programs, and academic-adjustment and mental-health-related services. Analogue or otherwise simulated therapeutic interactions and sensitivity or T-group experiences are omitted.

In keeping with traditional distinctions and definitions, individuals who have received postbaccalaureate, formal clinical training in professional programs of psychology, psychiatry, social work, and psychiatric nursing are considered to be professionals. Those who have not received this training are paraprofessionals.

The present review is divided into three sections. First, design criteria used to assess the methodology of comparative studies are described. Second, the characteristics and outcome of research studies are summarized, and the conclusions that present findings support are discussed. Third, experimental problems and limitations in current research are reviewed and suggestions for future work are offered.

The author wishes to thank Daryl "Kim" Hamblin for his help in the rating task described in this report.

Methodological Considerations

Luborsky, Singer, and Luborsky (1975) recently used 13 methodological criteria to evaluate the quality of research comparing alternative therapeutic approaches conducted by professionals. These criteria were modified for application to paraprofessional–professional comparative research. Two of the criteria used by Luborsky et al. regarding the need for experienced and mutually competent therapists were omitted, and two criteria, requiring multi-outcome and follow-up measures of client change, were added. The methodological criteria stressed such requirements as adequate sample size, equivalency of client groups, controls for expectancy effects and concurrent treatments, independent assessment of outcome, multi-outcome assessment of change, and at least one follow-up measure of client progress. For further details see Luborsky et al. (1975).

Forty-two studies comparing the effectiveness of professional and paraprofessional helpers were located. The experimental quality of each study was evaluated according to a 5-point index by applying the 13 design criteria. The grading system was not intended to be exact, but only to approximate the relative research sophistication of selected studies. As a partial check of the evaluation system, a second judge was asked to apply the criteria to five randomly selected studies. Interrater agreement was 92%.

Research Findings and Conclusions

Table 1 summarizes the characteristics, outcome, and experimental quality of the forty-two comparative studies. These studies represent a diversity of paraprofessional helpers, clinical settings, client populations, service programs, and target problems. Experienced psychologists, psychiatrists, and social workers typically constituted the professional therapist group. Only 10 studies exclusively used advanced clinical trainees as professional therapists (Elliott & Denney, 1975; Getz, Fujita, & Allen, 1975; Jensen, 1961; Kazdin, 1975; Levitz & Stunkard, 1974; Lindstrom, Balch, & Reese, 1976; Moleski & Tosi, 1976; Penick, Filion, Fox, & Stunkard, 1971; Ryan, Krall, & Hodges, 1976; Wolff, 1969).

The studies are grouped in Table 1 according to five major categories of helping services. The 19 studies in Group 1 involved individual and group psychotherapy or counseling primarily for moderately to severely disturbed adults; the four studies in Group 2 dealt with academic counseling for college students; the three studies in Group 3 involved crisis intervention for adults; and the 13 studies in Group 4 dealt with specific target problems of college students ($n = 5$), adults ($n = 6$), and children ($n = 2$), such as obesity, stuttering, insomnia, test and speech anxiety, and enuresis. Three studies fell into an *other* category (Group 5); these included Wolff's (1969) interpersonal training groups for normal college students, Schortinghuis and Frohman's (1974) cognitive tutoring program for handicapped preschool children, and Lamb and Clack's (1974) orientation program to a campus counseling center to increase use of this mental health resource among college students.

Thirty-five comparative studies have used multi-outcome measures of client change, and 27 studies have collected follow-up data on at least one measure. Representative outcome criteria have included performance on standardized psychological tests and various psychometric instruments (Lick & Heffler, 1977; Schortinghuis & Frohman, 1974), clients' self-reported change and satisfaction with services (Getz et al., 1975; Lamb & Clack, 1974), clinical ratings offered by independent judges (O'Brien, Hamm, Ray, Pierce, Luborsky, & Mintz, 1972), information from significant others (Miles, McLean, & Maurice, 1976; Wolff, 1969), academic or work performance (Mosher, Menn, & Matthews, 1975; Zunker & Brown, 1966), behavior ratings (Appleby, 1963; Ellsworth, 1968), analysis of therapist-offered empathy, warmth, and genuineness (Knickerbocker & McGee, 1973; Truax, 1967), performance in role-playing or in vivo situations (Fremouw & Harmatz, 1975; Moleski & Tosi, 1976), therapist improvement ratings (Karlsruher, 1976), supervisor evaluations (Covner, 1969; Magoon & Golann, 1966), criteria specific to treatment goals,

Table 1
Characteristics, Outcome, and Experimental Quality of Comparative Studies of Paraprofessional and Professional Helpers

Study	Experimental quality	Paraprofessional helpers	Client and helper sample size[a]	Results significantly favoring
Group 1: Individual or group psychotherapy or counseling				
Ellsworth (1968)	A	Psychiatric aides	327 psychiatric inpatients (?, ?)	Paraprofessionals
Jensen (1961)	B	Nurses and attendants	75 psychiatric inpatients[b] (?, 3)	Neither group
Karlsruher (1976)	B	College students	60 school children[b] (20, 6)	Neither group
Miles, McLean, & Maurice (1976)	B	Medical students	120 psychiatric inpatients (60, 27)	Neither group
O'Brien, Hamm, Ray, Pierce, Luborsky, & Mintz (1972)	B	Medical students	86 psychiatric outpatients (4, 12)	Neither group
Truax (1967)	B	Adult women	Over 300 vocational rehabilitation clients (4, 4)	Paraprofessionals
Truax & Lister (1970)	B	Adult women	168 vocational rehabilitation clients (4, 4)	Paraprofessionals
Weinman, Kleiner, Yu, & Tillson (1974)	B	Community volunteers	179 psychiatric outpatients (?, ?)	Neither group
Anker & Walsh (1961)	C	Occupational therapist	56 psychiatric inpatients (1, 1)	Paraprofessional
Appleby (1963)	C	Psychiatric aids	53 psychiatric inpatients[b] (?, ?)	Neither group
Colarelli & Siegel (1966)	C	Psychiatric aides	477 psychiatric inpatients (8, ?)	Neither group
Cole, Oetting, & Miskimins (1969)	C	Adult women	22 adolescent delinquents[b] (2, 2)	Neither group
Engelkes & Roberts (1970)	C	Adult counselors	1,502 vocational rehabilitation clients (142, 67)	Neither group
Mosher, Menn, & Matthews (1975)	C	Adult counselors	44 psychiatric inpatients (6, ?)	Paraprofessionals
Poser (1966)	C	College students	295 psychiatric inpatients[b] (11, 15)	Paraprofessionals
Sheldon (1964)	C	General physicians and nurses	83 psychiatric outpatients (?, ?)	Professionals better than physicians but equal to nurses
Mendel & Rapport (1963)	D	Psychiatric aides	166 psychiatric outpatients (?, ?)	Neither group
Covner (1969)	E	Community volunteers	Alcoholics[c] (?, ?)	Neither group
Magoon & Golann (1966)	E	Adult women	Psychiatric outpatients[c] (8, ?)	Neither group
Group 2: Academic counseling or advising for college students				
Zunker & Brown (1966)	A	College students	320 college students (8, 4)	Paraprofessionals
Brown & Myers (1975)	C	College students	303 college students (?, ?)	Neither group
Zultowski & Catron (1976)	C	College students	188 college students (10, ?)	Neither group
Murray (1972)	C	College students	166 college students (20, 9)	Neither group

Study	Experimental quality	Paraprofessional helpers	Client and helper sample size[a]	Results significantly favoring
Group 3: Crisis intervention for adults				
Knickerbocker & McGee (1973)	B	Community volunteers	92 adults and adolescents in crisis (65, 27)	Paraprofessionals
DeVol (1976)	E	Adult counselors	45 adults in crisis (4, 5)	Neither group
Getz, Fujita, & Allen (1975)	E	Community volunteers	104 adults in crisis (?, ?)	Neither group
Group 4: Interventions directed at specific target problems				
Kazdin (1975)	A	College students	54 unassertive adults and college students (?, ?)[d]	Neither group
Lick & Heffler (1977)	A	College student	40 adult insomniacs[b] (1, 1)	Neither group
Moleski & Tosi (1976)	A	Speech pathologist	20 adult stutterers[b] (1, 1)	Neither group
Elliott & Denney (1975)	B	College students	45 overweight college students[b] (3, 1)	Neither group
Levenberg & Wagner (1976)	B	Public health officer	54 adult smokers (1, 1)	Neither group
Levitz & Stunkard (1974)	B	Community volunteers	234 overweight adults[b] (8, 4)	Professionals
Lindstrom, Balch, & Reese (1976)	B	College students	68 overweight college students[b] (4, 1)	Neither group
Penick, Filion, Fox, & Stunkard (1971)	B	Adult volunteers	32 overweight adults (2, 1)	Neither group
Russell & Wise (1976)	B	College students	42 speech-anxious college students[b] (3, 3)	Neither group
Ryan, Krall, & Hodges (1976)	B	College students	72 test-anxious college students[b] (1, 2)	Neither group
Werry & Cohrssen (1965)	C	Parents	70 enuretic children[b] (22, 4)	Paraprofessionals
De Leon & Mandell (1966)	D	Parents	87 enuretic children[b] (56, 4)	Paraprofessionals
Fremouw & Harmatz (1975)	D	College students	30 speech-anxious college students[b] (11, 1)	Neither group
Group 5: Other interventions				
Lamb & Clack (1974)	B	College students	1,192 college students (?, 2)	Paraprofessionals
Schortinghuis & Frohman (1974)	C	Community volunteers	37 handicapped children (4, 3)	Paraprofessionals
Wolff (1969)	D	College students	88 college students[b] (4, 4)	Neither group

Note. A indicates that the design criteria were mainly satisfied; B, that one or two criteria were deficient; C, that three or four were deficient; D, that five were deficient; and E, that deficiencies were present in more than five criteria.
[a] Figures in parentheses are the number of paraprofessional and professional helpers, respectively; a ? indicates that the exact number of helpers was not specified.
[b] Includes no-treatment or attention-placebo control groups.
[c] Five therapists participated but a breakdown according to helper groups was not provided.
[d] Client sample size was not indicated.

such as weight loss or frequency of target behaviors (De Leon & Mandell, 1966; Levitz & Stunkard, 1974), and in hospital studies, such measures as length of hospital stay, ward transfers, discharge or readmission rates, and posthospital social and community adjustment (Jensen, 1961; Poser, 1966; Weinman, Kleiner, Yu, & Tillson, 1974).

Summaries of four studies involving psychiatric inpatients, children, adult insomniacs, and college students as clients are described below to provide the reader with some concrete examples of comparative research.

In a well-designed study, Zunker and Brown (1966) compared the effectiveness of four professional and eight student counselors who provided academic adjustment counseling to matched groups of 80 college freshmen. All counselors received 50 hours of identical training, used identical counseling materials, and followed an identical counseling sequence. Outcome criteria were assessments of study skills and study problems, academic grades, retention of information offered in counseling, and a counselor evaluation questionnaire. Student counselors were as effective as professionals on the first measure above but achieved significantly better results than did the professionals on each of the last four measures.

Lick and Heffler (1977) randomly assigned 40 adult insomniacs to four conditions: (a) therapist-administered progressive relaxation, (b) therapist-administered relaxation plus a taped relaxation program for client use at home, (c) placebo control, and (d) no-treatment control. A college undergraduate and a clinical psychologist saw clients in each treatment group. There were no outcome differences between the professional and paraprofessional therapists, as measured by client self-reported change and Minnesota Multiphasic Personality Inventory scores. The relaxation treatments did not differ significantly from each other, but both were significantly more effective than placebo and no-treatment controls.

In a child therapy study, 60 maladapting fifth and sixth graders were randomly assigned to a no-treatment control condition, treatment conducted by professional therapists (experienced school guidance counselors and psychology graduate students), or treatment by two groups of untrained college undergraduates who did or did not receive clinical supervision (Karlsruher, 1976). Treated children received 10 sessions of individual client-centered therapy. The California Test of Personality completed by the child, therapist improvement ratings, and a teacher-completed behavior checklist were used as outcome criteria. Children seen by supervised paraprofessionals improved the most, closely followed by children treated by professionals. Control children demonstrated more improvement than children seen by unsupervised paraprofessionals. Unexpectedly, ratings of therapist-offered empathy, warmth, and genuineness were negatively related to positive client change in the three treatment groups.

The progress of two matched samples of 60 psychiatric inpatients seen by medical student therapists, or psychiatric residents and fully trained psychiatrists was evaluated by Miles et al. (1976). Patients reported on changes in symptoms at the time of hospital discharge and again at 3-month follow-up. Independent ratings of improvement were also obtained from patients' significant others and family physicians at follow-up. From 40% to 88% of the patients demonstrated improvement on the outcome criteria at the different time points of evaluation, and there were no significant outcome differences between patients treated by the medical students, or psychiatrists and residents.

Overall, outcome results in comparative studies have favored paraprofessionals. In one study, professionals were more effective than one group of paraprofessional helpers but were equal in effectiveness to a second paraprofessional comparison group (Sheldon, 1964). In only one study were professionals significantly more effective than all paraprofessionals with whom they were compared (Levitz & Stunkard, 1974). In terms of measurable outcome, there were no significant differences among helpers in 28 investigations, but paraprofessionals were significantly more effective than professionals in 12 studies. The central finding from these comparative studies is that the clinical outcomes that paraprofes-

sionals achieve are equal to or significantly better than those obtained by professionals.

The provocative conclusion from these comparative investigations is that professionals do not possess demonstrably superior therapeutic skills, compared with paraprofessionals. Moreover, professional mental health education, training, and experience are not necessary prerequisites for an effective helping person.

In four studies (Anker & Walsh, 1961; De Leon & Mandell, 1966; Penick et al., 1971; Werry & Cohrssen, 1965) paraprofessionals have provided different treatment services from those provided by professionals, so it is not possible to assess therapist and treatment effects separately. Results could be due as much to the alternative treatment as to the use of paraprofessionals. Although these therapist–treatment confounds are a serious methodological drawback, the results of these four studies are heuristic. Paraprofessionals were found to be significantly more effective than professionals in three of these four studies (Anker & Walsh, 1961; De Leon & Mandell, 1966; Werry & Cohrssen, 1965) and such data challenge professionals to look more closely at the nature and efficacy of traditional mental health practices.

On closer scrutiny, results offer stronger support for paraprofessionals in some program areas than in others. The strongest support for paraprofessional effectiveness has come from the Group 4 studies, those directed at the modification of specific target problems. This group of studies contains the only one reporting results significantly favoring professionals (Levitz & Stunkard, 1974), but the other 12 studies showed no outcome differences among helper groups, and 10 of the 13 Group 4 studies were of A or B experimental quality (see Table 1 above).

The studies involving individual or group psychotherapy or counseling (Group 1) contained the largest number of studies favoring paraprofessionals over professionals (7), but only 3 of these 7 and 8 of the total group of 19 studies were relatively well controlled (of A or B quality). The lack of more rigorous research evaluation in Group 1 studies is unfortunate. These studies involved moderately to severely disturbed clients, and one can argue that such therapeutic programs are clinically more demanding than interventions attempting to modify discrete problem behaviors.

Academic counseling for college students, crisis intervention for adults, and the *other* interventions (Groups 2, 3, and 5, respectively) have not yet been carefully evaluated to offer any strong conclusions regarding paraprofessionals' clinical skills compared with those of professionals in these areas.

Current evidence offers reasonable, initial support for paraprofessionals' clinical effectiveness in comparative studies based on the following three considerations:

1. On the whole, the experimental quality of the studies in Table 1 approached or exceeded that observed in reviews of outcome research in other clinical areas (Bednar & Lawlis, 1971; Cash, 1973; Gurman, 1973; Kelley, Smits, Leventhal, & Rhodes, 1970; Luborsky, Chandler, Auerbach, Cohen, & Bachrach, 1971). Although some comparative reports were of little evaluative worth, others were relatively better controlled investigations on which at least tentative conclusions can be based.

2. Results are consistent regardless of the research sophistication of the study. Convergent evidence obtained by independent investigators using different design strategies and methods of evaluation lends strength to obtained findings.

3. Finally, several studies contained biases against paraprofessional treatment (Colarelli & Siegel, 1966; Fremouw & Harmatz, 1975; Jensen, 1961; Mendel & Rapport, 1963; Poser, 1966; Truax, 1967; Truax & Lister, 1970). Biases notwithstanding, positive findings of paraprofessionals' effectiveness suggest that a genuine clinical phenomenon is being observed.

Nevertheless, several reservations must be offered in evaluating the current status of comparative research. These issues are best discussed in reference to current experimental inadequacies and limitations and point the way toward future research.

Experimental Problems and Limitations

Design Criteria

The greatest deficiencies in design criteria were in the failure to assess the effects of additional, concurrent treatment (22 of 42 studies), to obtain multi-outcome (7 studies) or follow-up measures of client change (16 studies), or to rely on subjective estimates of treatment outcome (9 studies).

The criterion regarding the possibility of differential treatment expectations in the two helper-and-client groups was the most difficult to score. Although several authors noted biases against paraprofessional treatment (see above), a reverse bias was seldom noted. The initiation of a new treatment program, even if conducted by paraprofessionals, might create more positive expectations among staff and patients, in comparison with routine professional treatment. However, in most studies, it was difficult to determine whether this phenomenon was present.

The 13 design criteria adapted from Luborsky et al. (1975) are offered as a model to improve the methodology of future comparative research, with particular emphasis given to the most common deficiencies just mentioned. In addition to these design features, investigators should be aware of at least four other issues.

Patient Factors

The strongest evidence for paraprofessionals' effectiveness derives from studies of college students and adults with specific target problems (Group 4 studies) and moderately to severely disturbed non-middle-class adults (Group 1 studies). Work with adolescents is represented by a single study (Cole, Oetting, & Miskimins, 1969). Interventions with younger children concentrating on specific target behaviors have not been well controlled (De Leon & Mandell, 1966; Schortinghuis & Frohman, 1974; Werry & Cohrssen, 1965) and there has only been one study focusing on children's general adjustment difficulties (Karlsruher, 1976). No well-controlled comparative studies offering individual or group therapy have been conducted with clients, including college students, from the middle or upper socioeconomic classes. Since treatment effects might vary as a function of population characteristics, more comparative studies are needed dealing with the diverse problems of children, adolescents, college students, and adults not requiring psychiatric hospitalization or residential care.

Therapist Factors

Future work should examine the extent to which three therapist factors have contributed to current research findings—the use of unmatched therapist groups, the failure to study individual clinical performance, and the use of small therapist samples.

1. Paraprofessionals and professionals are frequently unmatched helper groups. In addition to formal clinical training and experience, paraprofessionals often differ from professionals in being younger, more often female, and from a lower socioeconomic class. The effects of these therapist variables in psychotherapy research are not clear (Meltzoff & Kornreich, 1970) but merit future study, especially in relation to therapy process dimensions and patient characteristics that may interact with outcome.

2. Individual clinical performance is seldom studied. It is possible that an emphasis on group performance obscures significant individual variability in helping effectiveness. By identifying certain workers who are particularly effective or ineffective within each helper group, the study of individual therapists' functioning might clarify the finding that on the average, paraprofessionals are able to do as well as professionals.

3. Finally, therapist samples in comparative studies are usually very small, yielding no indication of the representativeness of findings. Larger samples of paraprofessionals should be studied to provide information on the relative numbers and characteristics of personnel who can perform various clinical roles and functions adequately.

Selection Training and Supervision

Few studies have operationally defined their selection, training, and supervisory pro-

cedures, and fewer still have studied these program dimensions. Two studies comparing the presence versus absence of training and supervision obtained conflicting results. Karlsruher (1976) found that unsupervised and untrained college students were ineffective therapists for maladapting elementary school children, whereas untrained but supervised students and experienced professionals achieved equally successful results. In contrast, Lindstrom et al. (1976) reported that untrained and unsupervised college undergraduates were as effective as trained and supervised undergraduates and a professional therapist in helping college students lose weight.

Paraprofessionals have been selected on the basis of the results of psychological testing or a personal interview (Brown & Myers, 1975; Covner, 1969; Karlsruher, 1976; Russell & Wise, 1976), have been chosen because they were the working staff on clinical units or wards (Anker & Walsh, 1961; DeVol, 1976; Jensen, 1961; Miles et al., 1976; Moleski & Tosi, 1976), and have essentially been self-selected in the sense that available volunteers were accepted following apparently perfunctory screening procedures (Fremouw & Harmatz, 1975; Levitz & Stunkard, 1974; Murry, 1972; Poser, 1966). Most investigators, however, have not reported their selection process and criteria.

Some paraprofessionals have received no clinical training except a brief program orientation (Karlsruher, 1976; Lamb & Clack, 1974; Levenberg & Wagner, 1976; Poser, 1966; Weinman et al., 1974), some have received brief (up to 15 hours) training (Brown & Myers, 1975; Covner, 1969; Fremouw & Harmatz, 1975; Lindstrom et al., 1976; Levitz & Stunkard, 1974; Murry, 1972; Russell & Wise, 1976; Zultowski & Catron, 1976), and a few have participated in intensive programs approximating the training offered to professionals (Colarelli & Siegel, 1966; Magoon & Golann, 1966; Zunker & Brown, 1966). In most cases, only global descriptions of training programs have been presented. Both individual and group supervision have been used, but no one has detailed the supervisory process beyond clinical clichés.

Important parameters of selection, training, and supervision undoubtedly relate to program settings, treatment activities, goals, and client populations served. Judicious selection, training, and supervision might well account for paraprofessional effectiveness in comparative studies. Unfortunately, it is impossible to abstract the necessary details from comparative studies in order to analyze how paraprofessionals can be effectively selected, trained, and supervised. More systematic research should be devoted to these important program features.

The Process of Paraprofessional Intervention

Probably the most serious weakness in comparative research lies in the failure to examine the factors that account for paraprofessionals' effectiveness. Investigators have failed to relate specific intervention techniques to specific client changes. The nature of paraprofessional treatment is frequently left unclarified or is defined in global, undifferentiated terms. The nature of the paraprofessional's therapeutic influence is therefore undetermined.

Theories abound but evidence is meager about why nonprofessionals are effective helpers. For example, it is not known if paraprofessionals capitalize on powerful, nonspecific (placebo) therapeutic influences, use natural helping skills that perhaps reside in their interpersonal style, or adopt intervention techniques previously identified as effective in studies of professional therapists.

Paraprofessionals' higher interest and enthusiasm may make them as or more effective than professionals, but it seems unreasonable that these factors would work uniformly in all studies. Moreover, the perceived prestige and expertise often attributed to professionals by clients would probably minimize differential therapeutic effects accruing to paraprofessionals as a result of their enthusiasm and interest. Two studies found that paraprofessionals offered significantly higher levels of empathy, warmth, or genuineness to their clients than professionals did (Knickerbocker & McGee, 1973; Truax, 1967). These dimensions could account for paraprofessionals' effectiveness in these investigations and in

other programs as well. However, this issue is complex. Karlsruher (1976) reported that therapist-offered empathy, warmth, and genuineness were negatively related to positive changes occurring in child clients. Furthermore, there is controversy regarding the construct validity of ratings of empathy and other client-centered variables (Avery, D'Augelli, & Danish, 1976; Chinsky & Rappaport, 1970).

Paraprofessional effectiveness in some studies may be due to the development of carefully standardized and systematic treatment programs (Elliott & Denney, 1975; Kazdin, 1975; Levenberg & Wagner, 1976; Lick & Heffler, 1977; Lindstrom et al., 1976; Russell & Wise, 1976). In these programs, treatment has consisted of a programmed series of activities. Presumably, the more intervention procedures that can be clearly described and sequentially ordered in a helping program, the easier it will be for less trained personnel to administer them successfully. Paraprofessionals may feel more comfortable and hold higher expectations than professionals when using standardized clinical procedures, and these factors could contribute to paraprofessionals' clinical effectiveness. Therefore, paraprofessional clinical success may be closely related to professionals' abilities to define, order, and structure effective sequences of helping activities when training or supervising paraprofessionals. Although systematic treatment programs have been well controlled and have provided the strongest evidence of paraprofessionals' helping skills (Group 4 studies), paraprofessionals have exercised a wide latitude of clinical responsibility in most comparative studies and have not followed standardized and predetermined therapeutic procedures.

In summary, it is frustrating to admit that we do not know exactly why paraprofessionals with relatively little clinical experience and training can achieve results equal to or better than those obtained by professionals. Future research should attempt to define, isolate, and evaluate the primary treatment ingredients of paraprofessional helping programs. Research is needed in which the behavioral dimensions of nonprofessional intervention are described and assessed in relation to overall treatment effectiveness and specific client change.

The experimental limitations of comparative research must be discussed in relation to two important issues regarding the use of paraprofessionals within the mental health field. The first of these concerns the establishment of paraprofessional associate of arts programs and other new career training. The second deals with claims for the value of the indigenous therapist in reaching and helping various client populations.

Paraprofessional Mental Health Manpower

The intent of many undergraduate degree programs is to produce mental health generalists, that is, workers with a variety of basic helping skills who can eventually carry out many of the functions traditionally performed by professionals. Currently, over 4,000 graduates are being produced annually by approximately 170 paraprofessional college-level training programs (Young, True, & Packard, 1976). Present comparative evidence, however, does not support the ability of paraprofessionals to function effectively in full-time service positions.

Comparative research has studied workers' performance in very limited clinical roles with specific client groups. Paraprofessionals have primarily offered one form of treatment to homogeneous client populations in short-term experimental programs. In addition, research has neglected to assess paraprofessionals' and professionals' relative abilities to perform other primary clinical skills normally required in permanent service positions, such as intake interviewing, diagnostic assessment and evaluations, consultative services, and data collection for research purposes.

Therefore, comparative data supporting the value and wisdom of assimilating paraprofessionally trained workers as full-time staff in the human services are not currently available and can be obtained only in more comprehensive clinical studies. Systematic information is needed about the long-term effectiveness of paraprofessionals, employing a variety of intervention techniques with diverse client populations. We also need information on the relative abilities of paraprofes-

sionals and professionals to perform other primary clinical skills, ranging from intake interviewing to consultation. Pilot investigations examining workers' relative skills in these areas have only recently begun (Gingerich, Feldman, & Wodarski, 1976; Sloop & Quarrick, 1974).

Indigenous Therapists

Comparative research has offered only partial support for the value of indigenous therapists, that is, workers similar to clients in background, life-style, and general personal and demographic characteristics. The only controlled evidence for the effectiveness of indigenous therapists has involved college students (Brown & Myers, 1975; Elliott & Denney, 1975; Fremouw & Harmatz, 1975; Karlsruher, 1976; Lamb & Clack, 1974; Lindstrom et al., 1976; Murry, 1972; Russell & Wise, 1976; Ryan et al., 1976; Wolff, 1969; Zultowski & Catron, 1976; Zunker & Brown, 1966).

However, the indigenous therapist has often been cited as the treatment agent of choice for low-income and minority group clients who have not received a fair distribution of services from professionals in the past. It is believed that indigenous therapists can establish rapport and identification with previously underserved populations, which makes them more effective than professionals working with the same groups. Unfortunately, there are no experimental data to support this assertion. In fact, data from two analogue and attitude studies indicate that Mexican-American clients perceive white professionals to be as trustworthy, understanding, and helpful as indigenous therapists (Acosta & Sheehan, 1976; Andrade & Burstein, 1973). The comparative effectiveness of indigenous and professional helpers working with noncollege populations awaits empirical documentation.

Summary

Findings from 42 studies comparing the helping effectiveness of paraprofessionals and professionals are consistent and provocative. The clinical outcomes paraprofessionals achieve are equal to or significantly better than those obtained by professionals. These data suggest that professionals do not necessarily possess demonstrably superior clinical skills, in terms of measurable outcome, when compared with paraprofessionals. Moreover, professional mental health education, training, and experience are not necessary prerequisites for an effective helping person. The strongest support for paraprofessionals has come from programs directed at the modification of adults' and college students' specific target problems and, to a lesser extent, from group and individual therapy programs for non-middle-class adults.

Although the above findings and conclusions must be offered tentatively due to deficiencies and limitations in the methodology of many studies, the consistency of positive findings supports the potential value of paraprofessional helpers. A set of 13 design criteria adapted from Luborsky et al. (1975) is offered as a guide to improve the experimental rigor of future research. Future investigators should pay particular attention to a number of unresolved issues:

1. What are the primary treatment ingredients in paraprofessional helping programs? What specific behavioral dimensions of paraprofessional intervention are associated with treatment effectiveness?
2. How variable is individual clinical effectiveness within paraprofessional helper groups? Is a minority or a majority of helpers responsible for the positive findings that have been obtained? Do individual differences in clinical success relate to client, treatment, or therapist characteristics?
3. What is the breadth of paraprofessionals' clinical competence? Are paraprofessionals effective on a long-term basis when working with diverse client populations and providing more than one form of treatment or service? Can paraprofessionals adequately perform those therapy-related skills that would be required of them in full-time service positions such as clinical interviewing and diagnostic assessments?
4. Are indigenous therapists the treatment agent of choice for any client populations? If so, what factors account for this finding? For example, in comparison with professionals,

is the supposition correct that indigenous helpers are more accepted by and more empathic toward clients similar to themselves? Furthermore, are these variables associated with therapeutic outcome?

5. Finally, what are the most effective means of selecting, training, and supervising paraprofessionals? Generally, attempts in these directions have been nonspecific in comparative research, due to the limited number of therapists studied. However, if future work continues to confirm paraprofessionals' treatment effectiveness in comparative situations, then the most judicious use of paraprofessionals will, in large part, depend on determining the most successful techniques for recruiting, training, and supervising these new workers.

This review has used a broad definition of helping that encompasses a wide range of settings, helpers, clients, treatments, and criterion variables. This generic assessment of paraprofessional functioning seems appropriate given the current lack of experimentally rigorous process and outcome research. A more limited review of specific treatment situations would not have afforded any greater scrutiny or insight into paraprofessionals' abilities. However, as future investigators achieve stricter control of therapist, treatment, and client characteristics, paraprofessionals' functioning under different circumstances can be assessed more accurately and reliably in order to challenge or qualify the general conclusions offered here.

Current findings are not offered as a polemic against professional treatment but as a stimulus to investigate the processes that facilitate behavior change. Data indicate that paraprofessionals can make an important contribution as helping agents, but the factors accounting for this phenomenon are not understood. We are presently recruiting and employing thousands of paraprofessionals in the human services without an adequate understanding of why such personnel are effective helpers. It would be a mistake to continue using paraprofessionals without more closely examining their skills, deficiencies, and limitations.

Learned Helplessness in Humans: A Review and Attribution-Theory Model

Ivan W. Miller III
Brown University and Butler Hospital
Providence, Rhode Island

William H. Norman
Section of Psychiatry and Human Behavior
Brown University and Butler Hospital
Providence, Rhode Island

Seligman's theory of learned helplessness and the current status of the research literature are reviewed, with a focus on five issues of the learned helplessness phenomenon: (a) nature, (b) etiology, (c) generalization, (d) individual differences, and (e) alleviation. Seligman's theory is seen as inadequate to account for present data in several areas, notably etiology and generalization. A revised model of learned helplessness in humans is presented that suggests that the individual's attributions of noncontingent failure experiences predict the degree and parameters of learned helplessness.

Seligman and Maier (1967) and Overmier and Seligman (1967) used the term *learned helplessness* to describe an interference with escape–avoidance behaviors produced in dogs by prior inescapable shock. Since these early studies, research bearing on learned helplessness has proliferated. Early work investigating the parameters of the phenomenon used dogs as subjects (Overmier, 1968; Seligman & Groves, 1970; Seligman, Maier, & Geer, 1968), and more recent studies have reported the occurrence of learned helplessness in cats (Thomas & Balter, in press), fish (Padilla, Padilla, Ketterer, & Giacolone, 1970), and rats (Braud, Wepman, & Russo, 1969; Maier, Seligman, & Soloman, 1969; Maier & Testa, 1975).

The dominant researcher and theorist in this area has been Martin E. P. Seligman, who has written extensively on the nature, etiology, and significance of the learned helplessness phenomenon (Seligman, 1973, 1974, 1975). Seligman's model[1] has broadened the scope of learned helplessness from animal behavior to a wide variety of human behaviors, including reactive depression, stomach ulcers, voodoo deaths, and child development (Seligman, 1975). Since the publication of the early animal work and the major exposition of Seligman's theory (Seligman, 1975), a substantial body of research has investigated the parameters of the learned helplessness phenomenon with human subjects. Recent reviews (Maier & Seligman, 1976) and critiques (Levis, 1976) of learned helplessness research and theory have focused primarily on animal research. In view of the considerable interest in this area of research and the

An earlier version of this manuscript was submitted by Ivan W. Miller III in partial fulfillment of the requirements for the doctoral degree at the University of Maine, Orono. Committee members Joel Gold, Richard Ryckman, and Gordon Kulberg made helpful comments on that preliminary draft.

The authors would like to thank R. Eric Nelson for his thoughtful comments on the final draft of this article.

Requests for reprints should be sent to Ivan W. Miller III, Butler Hospital, 345 Blackstone Boulevard, Providence, Rhode Island 02906.

[1] Seligman has recently presented a revised model of learned helplessness (Seligman, Note 1; Abramson, Seligman, & Teasdale, 1978). Since this revised model was presented during the preparation of the final draft of the present article, all references in the text to "Seligman's model" refer to his pre-1977 position. It should also be noted that the basic statements of Seligman's revised model are remarkably similar to those of the model presented in the second half of the present article. The present authors and Seligman (Note 2) regard this theoretical overlap to be the result of parallel, independent contributions; as such, these represent a situation that is unusual in psychology. The present article makes no attempt to review, critique, or integrate Seligman's revised theory with the model proposed here.

possible implications for human behavior, it seems appropriate at this time to review the learned helplessness research and theory with an explicit focus on studies using human subjects. The purpose of this article, then, is threefold: (a) to review the research literature concerning the phenomenon of learned helplessness in humans, (b) to assess the validity of Seligman's theory in view of recent research, and (c) to propose a new model of learned helplessness in humans.

In order to facilitate comparison of theoretical predictions and research findings, this article focuses on five salient issues concerning learned helplessness. (a) What is the nature of learned helplessness? (b) What are the necessary and sufficient conditions for development of learned helplessness? (c) Is learned helplessness a generalized human phenomenon, or is it confined to specific laboratory conditions? (d) What are the individual differences factors that affect learned helplessness? (e) What are the necessary and sufficient conditions for alleviation of learned helplessness? This article reviews the relevant research and theory for each of the above issues.

Before moving to an evaluation of the research findings, however, it is necessary to discuss the basic experimental paradigm used in learned helplessness research. In the typical study, subjects receive a *training phase* followed by a *test phase*. In the training phase, subjects are exposed to a *training task,* in which they receive (a) contingent (response-dependent) reinforcement, (b) noncontingent (response-independent) reinforcement, or (c) no treatment (control). After this training phase, the performance of the three groups is compared on a *test task,* in which reinforcement is contingent for all groups. Learned helplessness occurs when the subjects receiving noncontingent reinforcement in the training phase show deficits in the test phase relative to the contingent and control groups. Thus, learned helplessness refers to behavioral deficits produced by exposure to noncontingent outcomes.

The Nature of Learned Helplessness

Seligman (1975) suggested that learned helplessness consists of three interrelated areas of disturbance: (a) motivational, (b) cognitive, and (c) emotional. More specifically, Seligman hypothesized that learned helplessness "(1) reduces the motivation to control the outcome; (2) interferes with learning that responding controls the outcome; (3) produces fear for as long as the subject is uncertain of the uncontrollability of the outcome, and then produces depression" (Seligman, 1975, p. 56). In an attempt to explore the nature of learned helplessness and the validity of Seligman's hypotheses, this section of the article examines the changes in test-task performance reported in the learned helplessness research with human subjects. Thus, this section is concerned with the nature of learned helplessness as operationalized by performance in the test phase, and not with the training-phase conditions necessary to produce learned helplessness.

Cognitive and Motivational Deficits

We are aware of 23 studies that have attempted to demonstrate the occurrence of changes in performance due to a training phase in which the subjects' responses were independent of environmental outcomes. Two generalizations concerning the measurement of the changes in performance are immediately evident from a review of these studies. First, in an attempt to operationalize Seligman's proposed cognitive and motivational deficits, most studies have used a test task requiring development and use of cognitive problem-solving strategies. A smaller number of studies have investigated the emotional aspects of learned helplessness. Second, although a majority of these studies have reported performance deficits in the test phase, several studies (Roth & Bootzin, 1974; Roth & Kubal, 1975; Thornton & Jacobs, 1972) have reported increases in performance following a learned helplessness training phase. Since the relevant issues concerning this *facilitation effect* seem to lie in the training phase of learned helplessness, these studies are covered in the next section during the discussion of the necessary and sufficient conditions for the development of learned helplessness. The present section examines those studies that have reported significant performance deficits.

Five studies have attempted to replicate the type of task used in the animal research by utilizing an escape–avoidance task in the test phase and have found deficits with human subjects (Hiroto, 1974; Hiroto & Seligman, 1975; Klein & Seligman, 1976; Krantz, Glass, & Snyder, 1974; Thornton & Jacobs, 1971). Seven other studies have used an anagram-solution task (Benson & Kennelly, 1976; Gatchel, Paulus, & Maples, 1975; Gatchel & Proctor, 1976; Hiroto & Seligman, 1975; Klein, Fencil-Morse, & Seligman, 1976; Miller & Seligman, 1975; Miller & Gold, Note 3). In this task, subjects are given a series of anagrams with the same solution order. In both the escape–avoidance and anagram tasks, three dependent measures have generally been employed: (a) number of trials to escape (anagram solution) criterion, (b) number of failures to escape (solve anagram), and (c) mean escape (anagram solution) latency. The measure of number of trials to criterion was hypothesized to operationalize the cognitive deficit, and the latter two measures were hypothesized to operationalize the motivational deficit. However, as was noted by Miller and Seligman (1975), because solution criteria were defined in terms of response speed, separation of motivational and cognitive components was not possible.

It is also important to note that the absolute magnitude of the deficits obtained in learned helplessness studies using escape–avoidance or anagram test tasks was relatively small. In the Hiroto and Seligman (1975) escape–avoidance task, for example, the mean response latency for the noncontingent group was about 8 sec, whereas the mean latency for the control group was about 7.3 sec. Although statistically significant, the small absolute difference raises questions about the importance of these results.

Two studies (Klein & Seligman, 1976; Miller & Seligman, 1975) designed to isolate Seligman's hypothesized cognitive deficit have employed Rotter, Liverant, and Crowne's (1961) measure of expectancy change following success or failure. In this task, subjects are given a "chance" or "skill" task, in which reinforcement is covertly manipulated by the experimenter. The dependent measure is the amount of expectancy change after trials of success or failure. Several studies (Phares, 1957; Rotter et al., 1961) have reported that reinforcement on previous trials had a greater effect on expectancies for future success when the subjects perceived reinforcement as response contingent. Unfortunately, the usefulness of this measure for learned helplessness depends on the previous research suggesting that expectancy change in this task is a function of the expectancy of response–outcome contingency. Other research investigating expectancy changes in this task (McMahan, 1973; Weiner, Nierenberg, & Goldstein, 1976) has suggested that expectancy changes following success and failure are not due to perceived response–outcome contingency but are due to the perceived stability of the causal attributions of performance. Hence, the use of the expectancy-change measure devised by Rotter et al. to operationalize an expectancy of response–outcome contingency remains highly questionable. This issue, as well as the construct of attributions, is examined in detail in a later section of this article.

Although other studies have used a variety of cognitive problem-solving tasks, including intelligence tests (Thornton & Jacobs, 1972), block design (Dweck & Reppucci, 1973), digit–letter substitution (Dweck & Bush, 1976), discrimination learning (Eisenberger, Park, & Frank, 1976), and specially designed concept-formation problems (Roth & Bootzin, 1974; Roth & Kubal, 1975), no study has adequately separated motivational and cognitive components of learned helplessness.

In summary, the literature pertaining to the performance changes produced by exposure to learned helplessness training conditions supports the conceptualization of learned helplessness as a performance deficit in cognitive problem-solving tasks. This deficit, though statistically significant, is relatively small in an absolute sense. The available evidence does not allow a distinction between cognitive and motivational explanations for this deficit. Thus, the performance deficits that are defined as learned helplessness may have a cognitive or motivational basis, or they may result from the impairment of both processes.

Emotional Deficits

Six studies have investigated the emotional aspects of learned helplessness (Gatchel et al., 1975; Gatchel & Proctor, 1976; Griffith, 1977; Krantz et al., 1974; Miller & Seligman, 1975; Roth & Kubal, 1975). These studies generally support Seligman's hypothesis that learned helplessness involves feelings of anxiety and depression. Miller and Seligman (1975) and Gatchel et al. (1975) administered the Multiple Affect Adjective Check List (Zuckerman, Lubin, & Robins, 1965) before and after exposure to contingent and noncontingent reinforcement. Both studies reported significant increases in feelings of depression, anxiety, and hostility following noncontingent reinforcement. Griffith (1977) administered the Paired Anxiety and Depression Scale (Mould, 1975) before and after exposure to noncontingent conditions and reported significant increases in depression following noncontingent failure and significant increases in anxiety following noncontingent success. Similarly, Roth and Kubal (1975) and Krantz et al. (1974) administered questionnaires following the training phase and reported increases in feelings of helplessness, incompetence, stress, frustration, hostility, depression, anger, and fatigue. Two studies have investigated the emotional aspects of learned helplessness through physiological measures (Gatchel & Proctor, 1976; Krantz et al., 1974). Both studies reported that subjects exposed to learned helplessness training conditions showed lower levels of electrodermal activity, which is thought to be evidence of a lowered motivational state (Malmo, 1965), which has also been suggested to be associated with clinical depression (McCarron, 1973).

Thus, although the self-report and physiological data support Seligman's predictions of increased depression and anxiety following exposure to a learned helplessness induction, the self-report studies also suggest that exposure to these conditions results in increased hostility, a phenomenon neither predicted nor explained by Seligman's theory.

In summary, the available research generally supports Seligman's hypotheses concerning the nature of learned helplessness. Performance deficits appear attributable to cognitive and motivational deficits, although assessment of the relative contributions of these two processes has not been demonstrated. Similarly, Seligman's hypothesis concerning the emotional aspects of learned helplessness appears to be supported, although the observed increases in hostility were not predicted.

Two basic issues remain concerning the nature of learned helplessness. The first concerns the limited number of types of tasks that have been used in learned helplessness test phases. With a few exceptions, these tasks have been cognitive problem-solving tasks. Few other types of tasks have been used to investigate the effects of learned helplessness in other types of situations. The second issue concerns the degree of impairment found in human subjects. All of the helplessness effects reported with humans have been relatively small, with no reports of any behavior as disabling as was found in the earlier research with infrahumans. There are certainly ethical and legal reasons for not attempting to instill these deficits in humans, but the consistent findings of small difference between groups raises questions concerning the relative significance of learned helplessness in humans. Animal research may provide a reasonable facsimile, or it may not. It is certainly possible that the superior cognitive strategies available to humans prevent the extreme effects of learned helplessness. This question of the relevance of animal research for a theory of learned helplessness is discussed in a later section.

Etiology

Seligman (1973, 1974, 1975) has postulated that the major causal factor in the development of learned helplessness is the organism's belief or expectancy that its responses will not influence the future probability of environmental outcomes (expectancy of response–outcome independence). He has further proposed that information about this contingency is a property of the environment, not of the organism, but that this information is transformed into an expectancy of the response–outcome contin-

gency, and it is this internal expectancy that directs behavior. In the learned helplessness paradigm, it is only when the organism forms the expectancy that its response will not be effective that learned helplessness is predicted to occur. Seligman has also briefly mentioned three variables that may limit the acquisition of the expectancy of response independence and of learned helplessness: (a) previous response–outcome expectancies, (b) discrimination between situations, and (c) the relative importance of the situation. He has not discussed these variables in any detail, however, and has not integrated them into his general theoretical framework.

Before moving on to an examination of the research bearing on Seligman's theory, the purpose of this section should be clarified. In terms of the general experimental paradigm discussed in the introduction, this section is concerned with the training phase, that is, those experimental manipulations and conditions that have been used to operationalize Seligman's construct of response–outcome independence, and with the success of these manipulations in producing deficits in test-task performance.

Turning now to an examination of the research, all of the animal studies and over half of the studies using human subjects have used an uncontrollable aversive stimulus, either noise or shock, in the training phase of the learned helplessness experiment (Fosco & Geer, 1971; Gatchel et al., 1975; Gatchel & Proctor, 1976; Geer, Davison, & Gatchel, 1970; Glass & Singer, 1972; Hiroto, 1974; Hiroto & Seligman, 1975; Klein & Seligman, 1976; Krantz et al., 1974; Miller & Seligman, 1975, 1976; Sherrod & Downs, 1974; Thornton & Jacobs, 1971, 1972). In these studies, subjects were exposed to an instrumental escape–avoidance task. The contingent group could actually avoid or escape the aversive stimulus, but the noncontingent group's responses did not influence the presentation of the aversive stimulus. Although several of these studies have not used appropriate control groups (Wortman & Brehm, 1975), all studies using an uncontrollable aversive stimulus, except that by Thornton and Jacobs (1972), have reported that the noncontingent group showed significant performance deficits in the test phase. These studies offer support for Seligman's hypothesis by demonstrating that close replication of the experimental procedures used to induce learned helplessness in infrahumans will also lead to learned helplessness in humans.

However, these studies have provided only a partial test of the ramifications of Seligman's theory. Seligman (1975) suggested that learned helplessness will result not only from noncontingent aversive stimulation but from any noncontingent environmental outcomes, including positive reinforcement. One group of studies (Benson & Kennelly, 1976; Hiroto & Seligman, 1975; Roth & Bootzin, 1974; Roth & Kubal, 1975; Miller & Gold, Note 3) has attempted to test this more general hypothesis by inducing learned helplessness by exposure to noncontingent positive reinforcement. All of these studies have used the procedure first reported by Roth and Bootzin (1974), who exposed subjects to contingent or random (noncontingent) reinforcement concerning their performance on a series of concept-formation discrimination tasks, as were described by Levine (1971). Roth and Bootzin argued that the condition of random reinforcement corresponded to Seligman's theoretical condition of independence of responses and outcomes but was not confounded by the effects of exposure to aversive stimulation. The results of studies using this type of training condition have been mixed. Hiroto and Seligman (1975) and Benson and Kennelly (1976) reported that random-reinforcement groups showed deficits on an anagram test task, relative to contingent-reinforcement and control groups. Conversely, Roth and Bootzin (1974) reported a facilitation of performance following exposure to this type of training task. Roth and Kubal (1975) varied the number of tasks in which the subjects received random reinforcement. They reported that subjects exposed to only one learned helplessness training task showed facilitation effects, whereas subjects exposed to random reinforcement in two different training tasks showed deficits on the same test task. These results, however, have not been replicated (Kilpatrick-Tabak & Roth, Note 4). It should be noted that the test tasks used by

Roth and Bootzin (1974) and Roth and Kubal (1975) differed from those used by Hiroto and Seligman (1975) and Benson and Kennelly (1976) on several dimensions, notably on the similarity of the training and test phases. (These differences are discussed more thoroughly in a later section.)

In general, it is apparent that the results from studies using a random-reinforcement procedure have been far from definitive. Furthermore, the use of random reinforcement as noncontingent positive reinforcement is questionable. Benson and Kennelly (1976) cogently argued that since nonreward in the context of reward produces frustration, an aversive event (Amsel, 1972), a random schedule of rewards means that reward and frustration may also occur in a random and uncontrollable manner. A random-reinforcement procedure can thus be seen as confounding noncontingent positive reinforcement with noncontingent aversive stimulation.

Not only does a random-reinforcement procedure confound the type of noncontingent outcome, it also confounds the absolute amounts of positive and negative outcomes that occur. Studies using a random-reinforcement group have typically not yoked the noncontingent (random) group's reinforcement to the contingent group's level, as was done in the early animal studies, but instead have fixed the random group's reinforcement rate at 50%. Thus, the obtained differences between groups may be due to differences in the amount and pattern of reinforcement received.

Two studies (Benson & Kennelly, 1976; Miller & Gold, Note 3) have controlled for the amount and type of reinforcement. Miller and Gold used three groups in the standard Levine (1971) discrimination-problem training task: (a) contingent (80% correct), (b) yoked noncontingent (80% correct), and (c) random (50% correct). They reported that the yoked and random groups showed significant deficits on a later anagram task, relative to the contingent group, but the yoked group performed significantly better than the random group. In addition to contingent, random, and control groups, Benson and Kennelly (1976) used a noncontingent 100% correct group and found no significant differences between the contingent group and the noncontingent/correct group on a later anagram test task, even though the noncontingent/correct group reported having no control over outcomes. Thus, noncontingent positive reinforcement does not appear to produce learned helplessness.

Taken together, these two studies provide evidence that the type and amount of reinforcement directly influence the development of learned helplessness. Similarly, although studies combining noncontingency with a clearly aversive outcome have consistently produced learned helplessness, other studies using the random-reinforcement procedure, which can be seen as alternating noncontingent positive and noncontingent negative reinforcement, have reported mixed results. The overall pattern of results, however, suggests that noncontingent reinforcement is not a necessary and sufficient condition for the development of learned helplessness but that both the contingency and the nature of the obtained outcome are critical to learned helplessness.

In addition to the basic issue of what type of conditions are necessary to produce learned helplessness, there are several other variables that have been shown to exert a significant influence on the development of learned helplessness, including (a) instructional set, (b) task importance, and (c) attributions of performance.

Instructional Set

Instructions given to subjects in the experimental situation regarding response–outcome contingencies have been shown to affect the development of learned helplessness (Geer et al., 1970; Glass & Singer, 1972; Hiroto, 1974). For example, Glass and Singer told subjects they could push a button that would turn off an aversive tone but that the experimenter would "prefer you didn't use it." This procedure significantly increased problem-solving performance during exposure to the tone, relative to those subjects who were not told they had control of the noise. Similarly, Hiroto (1974) reported that sub-

jects who were given instructions that onset of an aversive stimulus was contingent on their responses were significantly less helpless than those subjects who were told the experimenter was controlling the aversive stimulus.

Although not discussed specifically by Seligman, the above results are congruent with the focus of his theory. Since Seligman (1975) posited that behavior is motivated by an internal, cognitive expectancy, these experimental instructions can be viewed as one way of manipulating expectations. For example, Hiroto's (1974) "chance" instructions represent another procedure that induces an expectancy similar to that induced by an experience with an inescapable aversive stimulus (i.e., an expectancy that responses and outcomes are noncontingent), which also results in similar decrements in performance. Similarly, as in the Glass and Singer (1972) study, instructions specifying that responses do control outcomes produce a positive expectancy and no deficits in performance. Thus, instructional set regarding the reinforcement contingencies appears to be a crucial variable for inducing learned helplessness.

Task Importance

Instructions regarding the relative significance of the experimental task have also been shown to influence the development of learned helplessness. As is mentioned above, Seligman (1975) briefly mentioned the effects of task importance but did not elaborate this prediction. Two studies (Roth & Kubal, 1975; Miller & Gold, Note 3) have directly investigated the effect of instructions regarding task importance on the development of learned helplessness. In both studies, importance was manipulated by instructing college student subjects that the training and test tasks were measures of scholastic aptitude and intelligence. Subjects exposed to noncontingent reinforcement showed significantly greater helplessness in the *important* conditions than in the *unimportant* condition. Using contingent, yoked-noncontingent, and random-reinforcement groups, Miller and Gold found no differences between *unimportant* groups but significant differences between all *important* groups. Similar results were reported by Roth and Kubal (1975). These studies strongly support the hypothesis that the perceived importance of the experimental task is a potent factor in the development of learned helplessness and can be manipulated by experimental instructions.

Attributions of Performance

Five studies (Dweck, 1975; Dweck & Reppucci, 1973; Klein et al., 1976; Tennen & Eller, 1977; Wortman, Panciera, Shusterman, & Hibscher, 1976) have investigated the role of the subject's attributions of task performance in the development of learned helplessness. Attribution theory (Weiner, Frieze, Kukla, Reed, Rest, and Rosenbaum, 1971) postulates that the individual's causal attributions influence his or her expectations for probable outcomes of future performance. In learned helplessness, attribution theory would suggest that the subject's attribution concerning the noncontingency of reinforcement would influence both one's expectations and one's performance in future tasks. The research investigating this hypothesis has generally been supportive. Dweck and Reppucci (1973) reported that following experience with noncontingent failure (unsolvable block designs), those children who showed the most performance deficits tended to attribute success or failure to ability; conversely, those children who showed fewest deficits tended to attribute their performance to effort. Dweck (1975) continued this line of research by developing a treatment program for "naturally occurring" helpless children, that is, those who were more adversely affected by failure. In her treatment program, Dweck taught these "helpless" children to attribute failure to lack of effort. Following this "reattribution training," these children showed significant improvements in task persistence and less helplessness than did a group treated with "success-only" experiences, who showed no differences from baseline.

In another study concerning attributions and learned helplessness, Klein et al. (1976) directly manipulated attributions by informing subjects about other subjects' task per-

formance. In the internal-attribution condition subjects were told that 55% of previous subjects succeeded in all problems, and in the external-attribution condition they were told that 90% had failed on all problems. Following these instructions, depressed and nondepressed subjects were exposed to random reinforcement in a discrimination task followed by an anagram test task. Klein et al. reported that the attribution instructions did not significantly affect the nondepressed subjects, but for the depressed subjects the external instructions alleviated learned helplessness on the anagrams. Klein et al. suggested that helplessness and depression are due to both failure and attribution of that failure to personal incompetence.

The results obtained by Tennen and Eller (1977) also support this hypothesis. They exposed subjects to a double helplessness condition, in which subjects were told that each succeeding task was either easier or more difficult. The results indicated that the *easier* group, who presumably made attributions to ability, showed learned helplessness but that the *more difficult* group, who presumably made attributions to task difficulty, did not. Thus, three studies (Dweck & Reppucci, 1973; Klein et al., 1976; Tennen & Eller, 1977) have suggested that attribution of noncontingent failure to ability or personal competence leads to increased learned helplessness, whereas attribution of these outcomes to situational factors or task difficulty does not produce learned helplessness.

One recent study (Wortman et al., 1976) reported findings that appear contradictory to this hypothesis. However, a closer examination of the methodology of this study reveals significant differences between this study and the studies previously described. Wortman et al. told their subjects that their study would deal with the effects of noise on performance and that the amount of noise would be contingent on their performance on several problems. Subjects were then exposed to unavoidable noise and were told they had failed to solve any of the problems. Three information conditions were used: (a) no information, (b) information that another subject could solve the problems (incompetence condition), and (c) information that another subject could not solve the problems (task-difficulty condition). The results indicated that the incompetence group felt more helpless and stressed but performed better than the task-difficulty group did when the same problems were presented later without the noise. Although these results appear contradictory to previous studies, a closer analysis of the methodology clarifies the discrepancy. As was pointed out by Tennen and Eller (1977), the incompetence condition in the Wortman et al. study exposed subjects to a situation in which (a) they were told that the study was about the effects of noise on performance, and (b) another person's performance did not seem to be affected by noise, whereas their own performance under noise conditions was poor. It seems that the most likely attribution of this situation would be that the subject had difficulty solving problems with accompanying noise. Thus, when problems were presented later without noise, the subjects in the incompetence group would expect their performance to improve and would be motivated to attempt to do so. Alternatively, the task-difficulty group, who thought that their failure was due to the difficulty of the task, could not expect any change in their outcomes and thus would have been less motivated to attempt solutions on later problems. Viewed from this perspective, the incompetence group did not produce attributions to the general quality of *competence*, but produced attributions to the relatively specific cause of *ability to solve problems with noise present*, and as such, the incompetence condition was not equivalent to the ability or competence conditions of previous studies.

It is evident from these studies that attributions of noncontingent failure experiences are a potent factor in the development of learned helplessness, with attributions to competence resulting in increased deficits. The implications of these results concerning the effects of attributions are very suggestive and will form the basis of the revised model of learned helplessness proposed in the last section of this article.

More generally, the research reviewed suggests that several variables (task instructions, task importance, attributions) appear to exert significant influences on the development of learned helplessness. Also, these variables appear to be mutually interactive. Since studies have neither varied nor controlled for all of these variables, the relative contribution and specific interactions are difficult to specify at this time.

Facilitation

Although exposure to noncontingent reinforcement has generally been found to result in performance deficits, several studies (Roth & Bootzin, 1974; Roth & Kubal, 1975; Shaban & Welling, cited in Glass & Singer, 1972; Tennen & Eller, 1977; Thornton & Jacobs, 1972; Wortman et al., 1976) have reported improved performance (facilitation) on a later dissimilar task following exposure to a learned helplessness training phase. Since these facilitation effects are at odds with Seligman's basic hypothesis, they deserve closer examination.

Roth and her co-workers (Roth & Bootzin, 1974; Roth & Kubal, 1975) have suggested that these results point to a curvilinear relationship between the amount of exposure to noncontingent reinforcement and learned helplessness. They have proposed that a moderate degree of exposure will result in a greater degree of responding or facilitation, whereas more exposure will result in deficits due to learned helplessness. Seligman (1975) briefly mentioned a similar hypothesis, but only in his argument concerning emotional responses to trauma. He suggested that the organism's initial reaction to uncontrollability is fear, activity, and overresponding, and that continued uncontrollable trauma leads to learned helplessness and depression. Similar predictions were made by Wortman and Brehm (1975) in their integration of reactance theory and learned helplessness.

Since experimental documentation of this hypothesized curvilinear relationship between an amount of exposure and learned helplessness requires at least two levels of exposure to noncontingent reinforcement, only two of the studies reporting facilitation have offered direct evidence concerning this hypothesis. In the first study, Roth and Kubal (1975) varied the amount of exposure to noncontingent outcomes. They reported that subjects exposed to the single helplessness condition showed facilitation effects and that the subjects in the double helplessness condition showed deficits. Analyses of their data also showed significant quadratic trends. These results appear to support Roth and Kubal's hypothesis, but Tennen and Eller (1977) argued that since the instructions of Roth and Kubal's double helplessness condition told the subjects that each succeeding task was "a little bit easier," the Roth and Kubal study confounded the amount of exposure with attribution instructions. Following attribution theory (Weiner et al., 1971), Tennen and Eller hypothesized that attributions to ability (an internal, stable cause) would lead to helplessness, whereas attributions to task difficulty (an external, variable cause) would lead to facilitation. Tennen and Eller tested this hypothesis by replicating Roth and Kubal's study with the addition of a double helplessness condition in which subjects were told that the tasks were becoming more difficult. On a later test task, the double-helplessness "easier" group showed helplessness deficits, and the double-helplessness "more difficult" group showed facilitation effects.

Although the available evidence concerning facilitation effects suggests that a minimum level of exposure to noncontingent outcomes may result in facilitation whereas increased amounts of exposure to noncontingent outcomes may result in learned helplessness, there is evidence that these effects are mediated by the subject's attributions of performance.

In summary, the studies reviewed concerning the etiology of learned helplessness partially support Seligman's hypothesis regarding the necessary and sufficient conditions for the development of learned helplessness. The results of this review indicate that development of learned helplessness requires exposure to environmental conditions in which outcomes are independent of responses *and* are nondesired or aversive to the individual.

The research has also identified four variables (amount of exposure, instructions concerning contingency, task importance, and attributions) that affect the development of learned helplessness and appear to be mutually interactive. Although Seligman's theory briefly discusses the possible effects of instructions and situational importance, it disregards attributions entirely. Furthermore, the focus of the effects of instructions, task importance, and attributions appears to lie in the cognitive processes of the individual, which Seligman does not address beyond the use of a simple expectancy construct. This lack of specification of cognitive processes influencing the development of learned helplessness appears to be a critical deficiency. Finally, a number of studies have reported improved performance following exposure to noncontingent failure outcomes, a phenomenon neither predicted nor explained by Seligman's theory.

Individual Differences

Seligman has not explicitly included any individual differences variables in his formulations of learned helplessness. However, several studies have reported individual differences following exposure to a learned helplessness training phase. Hiroto (1974) reported that subjects scoring in the external direction on Rotter's (1966) Internal–External Locus of Control Scale showed greater performance deficits after exposure to noncontingent reinforcement than did internals. Miller and Seligman (1975), however, did not report differences on this variable. Krantz et al. (1974) investigated the performance of Type A and Type B coronary-prone individuals after exposure to noncontingent reinforcement. They reported significant differences in the responses of Type A and Type B subjects to noncontingent reinforcement. Furthermore, these differences appeared to be a function of the interaction of noncontingency and the intensity of the aversive stimulus, and are consistent with descriptions of these two personality types.

Another individual differences variable that has received some attention in the learned helplessness literature is gender. Although the great majority of learned helplessness studies have not analyzed sex differences, two studies (Dweck & Bush, 1976; Dweck & Reppucci, 1973) have pointed out the possible effects of sex differences in response to noncontingent reinforcement. Dweck and Reppucci (1973) reported that male children attributed outcomes to the amount of effort more often than did female children, and attributions to effort resulted in significantly smaller performance deficits. In a more intensive study, Dweck and Bush exposed male and female children to noncontingent failure from both an adult and a peer evaluator. Failure feedback from adults resulted in impaired performance for girls but in improved performance for boys. Similarly, when a peer evaluator was used, boys showed no performance increases, whereas girls' performance improved significantly. Also, children's attributions of failure varied with the type of evaluator, with boys attributing failure to the amount of effort with the adult evaluator but to their own abilities in the peer situation. Again, girls showed opposite effects, attributing performance to ability with the adult evaluator and to effort with a peer. Although these two studies were done with children and were preliminary, they do offer evidence that there may be sex differences in response to learned helplessness and, furthermore, that attributions of performance may mediate this effect.

Seligman (1974, 1975) has also suggested that reactive depression and learned helplessness are similar disturbances, with common etiology, symptoms, course, and cure. It is not the purpose of this article to discuss the validity of learned helplessness as a model of depression (see Blaney, 1977; Eastman, 1976; Seligman, 1974, 1975), but a brief discussion of the similarities in performance of depressed subjects and subjects exposed to a learned helplessness training phase seems appropriate. Six studies have investigated these similarities and have reported that nondepressed subjects exposed to a learned helplessness training phase perform similarly to depressed subjects on a variety of test tasks, including expectancy changes (Klein & Seligman, 1976; Miller, Seligman, & Kurlander,

1975; Miller & Seligman, 1973, 1976), escape–avoidance learning (Klein & Seligman, 1976), and anagram solution (Klein et al., 1976; Miller & Seligman, 1975). Conversely, exposure to a learned helplessness training phase has not increased performance deficits observed among depressed subjects (Klein et al., 1976; Miller & Seligman, 1975). Thus, Seligman's hypothesis regarding the similarities of depression and learned helplessness has been supported by the available research. It must be noted, however, that all of these studies used nonclinically depressed college students, and the generalizability and relevance of these results for clinical depression remains to be demonstrated.

Although the few studies investigating the effects of individual differences variables and learned helplessness have produced significant results, individual differences, except for depression, have received little attention from learned helplessness research or theory. Since there are both theoretical arguments (Cronbach, 1975; Kiesler, 1971; Underwood, 1975) and empirical evidence (Bowers, 1973; Moos, 1969) suggesting that Person × Situation interactions will provide a more accurate conceptualization of behavior than will either dimension separately, future research and theory in the learned helplessness area should include discussion of these interactions and their effects.

Generalization

Generalization of performance deficits beyond the specific experimental task and situation is a major unresolved issue of the learned helplessness literature. The basic finding in the paradigmatic learned helplessness experiments has been that subjects tend to overgeneralize experiences in the training phase to the later test phase. Subjects exposed to aversive situations in which responses do not influence outcomes overgeneralize this noncontingency to later situations in which responses do influence outcomes. The relative significance of the learned helplessness paradigm is largely tied to the degree of generalization that occurs. Roth and Bootzin (1974) stated the issue succinctly: "The major question is whether an induced external expectancy generalizes to a new situation, not whether it controls behavior in the situation in which it is induced" (p. 255). Clearly, a reduction of responding in a situation in which responses do not influence outcomes is an *adaptive* behavior. It becomes maladaptive only when it is transferred or generalized to new situations in which outcomes are contingent on responses.

Seligman (1975) argued that "men and animals are born generalizers. . . . The learning of helplessness is no exception" (p. 35). He proposed that learned helplessness is a general phenomenon that influences many different aspects of an individual's life. In short, he suggested that learned helplessness can be viewed as a generalized personality trait, which influences behavior in a wide range of situations.

Unfortunately, the evidence concerning the generalizability of deficits caused by learned helplessness inductions is not definitive. Most learned helplessness studies have used test phases in which the type of task and the situational conditions were similar to those of the training phase (Benson & Kennelly, 1976; Dweck & Bush, 1976; Eisenberger et al., 1976; Fosco & Geer, 1971; Hiroto, 1974; Hiroto & Seligman, 1975; Klein & Seligman, 1976; Krantz et al., 1974; Miller & Gold, Note 3). Other studies have demonstrated generalization across types of tasks, when the training and test situations have been similar (Gatchel et al., 1975; Gatchel & Proctor, 1976; Hiroto & Seligman, 1975; Miller & Seligman, 1975; Thornton & Jacobs, 1972). That is, generalization has been reported when subjects perceived that the training and test phases were both part of the same experiment. These studies have not investigated the degree of situational generality of the learned helplessness. Hiroto and Seligman (1975) recognized this shortcoming of their study:

> One limitation on the generality of these effects should be mentioned. The subjects clearly perceived both tasks, as different as they are, as part of the same experiment. We do not know whether any learned helplessness was carried out of the laboratory. (p. 326)

The critical nature of the situational similarity between learned helplessness training and test phases is shown in the Dweck and Reppucci (1973) study, in which children were given a set of unsolvable problems by one teacher and a set of solvable ones by another. Later, these children were administered a similar set of solvable problems by both teachers. The children showed significantly poorer performance when the problems were administered by the teacher who had previously given unsolvable problems. In this study, even though the training and test tasks were identical, the stimulus, namely, the teacher, influenced the children's performance. The children did generalize the experiences of the training phase maladaptively, but the generalization was tied to the situational characteristics in which the learned helplessness was produced.

Other studies have investigated the generalization issue by using a test phase that was situationally dissimilar from the training phase (Roth & Bootzin, 1974; Roth & Kubal, 1975; Sherrod & Downs, 1974; Tennen & Eller, 1977; Wortman et al., 1976; Kilpatrick-Tabak & Roth, Note 4). Of these six studies, three (Roth & Kubal, 1975; Sherrod & Downs, 1974; Tennen & Eller, 1977) reported deficits in their test phase, and three other studies (Roth & Bootzin, 1974; Wortman et al., 1976; Kilpatrick-Tabak & Roth, Note 4) reported no deficits. The studies that did obtain cross-situational generalization had two common factors: (a) prolonged exposure of subjects to noncontingent failure outcomes, and (b) instructions designed to induce an attribution of task performance to ability. Studies that have not exposed subjects to these two conditions have not found cross-situational generalization. Conversely, one study (Kilpatrick-Tabak & Roth, Note 4) exposed subjects to these conditions and did not obtain generalization. Thus, cross-situational generalization of learned helplessness has not been conclusively demonstrated at this time.

In summary, there is evidence that learned helplessness generalizes from one type of task to another, but there is no conclusive evidence regarding the degree of generalization across situations, and no study has varied both situational and task dimensions. The failure to demonstrate cross-situational generalization is a major flaw in the learned helplessness literature. Without conclusive evidence for generalization, the significance of the learned helplessness phenomenon becomes questionable. Unfortunately, Seligman's theory does not address the issue of generalization in any detail and does not adequately specify the determinants of generalization of learned helplessness. If learned helplessness is to represent an adequate analogue of depression, then a detailed statement of how and when generalization will occur and relevant research are essential.

Alleviation

Drawing on the animal research, Seligman (1975) suggested that learned helplessness could be "cured" by the establishment of an expectancy that outcomes are dependent on responses. In the case of dogs in the shuttle box, this "therapy" consisted of repeatedly pulling dogs to the safe side of the box until they learned that their movement affected the offset of the shock. Four studies have attempted to alleviate deficits caused by learned helplessness inductions in humans. Of these, three (Dweck, 1975; Klein & Seligman, 1976; Kilpatrick-Tabak & Roth, Note 4) employed procedures in which subjects were given response-dependent feedback concerning their performance on a task interposed between training and test tasks. Klein and Seligman (1976) exposed nondepressed subjects to inescapable noise and then exposed half of these "helpless" subjects and depressed subjects without pretraining to a treatment of either 4 or 12 discrimination problems with response-dependent feedback. They reported that on a subsequent escape–avoidance task, both treatment groups showed significantly better performance and a greater expectancy of response–outcome dependence than did subjects in the no-treatment groups. This study closely paralleled the earlier research with dogs and supported Seligman's hypothesis that exposure to response-dependent outcomes reduces learned helplessness.

A second study that attempted to alleviate learned helplessness was done by Kilpatrick-Tabak and Roth (Note 4). In this study, subjects selected without respect to depression were exposed to a training phase used by Roth and Kubal (1975). These subjects and depressed subjects without pretraining were then exposed to one of four treatments: (a) reading Velten's (1968) list of positive self-statements, a procedure that may be broadly conceptualized as a cognitive, possibly reattributional task; (b) solution of a set of simple anagrams; (c) waiting alone for 15 minutes; and (d) waiting with another person for the same time. All subjects, including a nondepressed control group without training or treatment exposure, were given the test task from Roth and Kubal's (1975) study. The results indicated that although both Treatments 1 and 2 were successful for the nondepressed, helpless group, they did not alleviate the deficits shown by the depressed subjects. In fact, exposure to simple anagrams increased later deficits in depressed subjects, a result quite contrary to Seligman's hypothesis. Although this study was compromised by the fact that the waiting-period groups did not differ from the control group on the test task, the failure of the treatment procedure (i.e., solving anagrams) to alleviate deficits in the depressed subjects conflicts with Seligman's hypothesis and the results of Klein and Seligman (1976). Thus, the evidence regarding Seligman's hypothesis is inconclusive at this time.

Two other studies (Dweck, 1975; Klein et al., 1976) have taken a different approach to alleviation of learned helplessness and have focused on the subjects' attributions of learned helplessness performance. Dweck (1975) selected children who were identified as "helpless" by several school personnel. She then exposed these children to one of two treatment conditions. The first treatment, "reattribution training," taught the children to attribute failure to a lack of effort. The second treatment, "success only," provided children with a variety of success experiences with no attribution training. The results indicated that the success-only group did not change from their baseline level of performance, whereas the reattribution group showed significant improvements from their baseline of performance. Unfortunately, the reattribution-training group included contingent practice, so conclusions of differential effectiveness cannot be attributed solely to the cognitive intervention. The most that can be concluded is that a package of response-dependent feedback and altered cognitions is superior to response-dependent feedback alone.[2]

Klein et al. (1976) reported that the performance of depressed subjects improved when they were told that most people failed the training task, an instructional set presumed to induce an attribution of task difficulty. However, the treatment used by Klein et al. did not improve the performance of nondepressed subjects exposed to response-independent failure outcomes.

In summary, the literature pertaining to the alleviation of learned helplessness provides few clear conclusions. Naturally occurring performance deficits found in depressed college students and children have been improved by reattribution therapy (Dweck, 1975; Klein et al., 1976) and, in one study, by exposure to response-dependent success conditions (Klein & Seligman, 1976). Another study, however, found that exposing depressed subjects to response-dependent success outcomes produced no improvement (Kilpatrick-Tabak & Roth, Note 4). On the other hand, deficits engendered in nondepressed college students have been alleviated successfully in two studies (Klein & Seligman, 1976; Kilpatrick-Tabak & Roth, Note 4) by exposure to response-dependent feedback, but Klein et al. (1976) reported that treating nondepressed college students with a reattribution treatment was not successful in alleviating the produced deficits. The two investigations that have compared response-dependent success and a cognitive manipulation either did not afford unconfounded interpretation (Dweck, 1975) or did not include a treatment focused on reattributing failure experiences (Kilpatrick-Tabak & Roth, Note 4). Thus,

present research does not allow conclusions concerning the relative effectiveness of these treatments.

Summary

As the preceding review demonstrates, Seligman's theory of learned helplessness no longer offers a full and viable explanation for the results of the current research. There are several areas in which Seligman's model seems inadequate to account for present data. The first area concerns the necessary and sufficient conditions for the development of learned helplessness. Although Seligman hypothesized that an expectancy of response–outcome independence is necessary and sufficient for learned helplessness to occur, current research suggests that an expectancy of response–outcome independence and a nondesired outcome are necessary for the development of learned helplessness. The second area in which Seligman's theory seems deficient is in regard to the other factors that effect learned helplessness. More specification is needed to explain how, why, and when variables such as instructions, task importance, and subject's attributions effect learned helplessness. The third area concerns generalization. Seligman's theory does not delineate the processes and circumstances under which learned helplessness will generalize. Since the relevance of the learned helplessness paradigm seems to hinge on generalization and present research has not documented generalization of learned helplessness, this is a most critical deficiency. The lack of integration of individual differences factors into learned helplessness theory is a fourth area of weakness. The final area concerns the alleviation of learned helplessness. Support for Seligman's hypothesis concerning the conditions necessary for alleviation of learned helplessness is equivocal, with attributions appearing to be a major factor.

More generally, research and theory in the learned helplessness area appear to be plagued by a narrowness of approach. First, the basic stance of Seligman's theory has largely been neglected by researchers. Seligman hypothesized that the cognitive expectancy of response–outcome independence, not the actual experience of exposure to those conditions, produces learned helplessness. Unfortunately, the learned helplessness research literature has focused primarily on the environmental conditions that seem to produce learned helplessness and have neglected the cognitive schema that Seligman postulated as crucial. Seligman's theory can be seen as contributing to this neglect because it does not elaborate the cognitive processes and variables relevant to learned helplessness. One reason for this deficiency may lie in the animal research origins of the learned helplessness paradigms. Dogs and rats simply do not have the cognitive complexity or construction abilities of humans. As was pointed out by Levis (1976), Seligman's theory equates the cognitive processes of humans with those of a cockroach. This article takes the position that the explanation of human behavor requires more complex and detailed hypotheses regarding the function of cognitive processes. The learned helplessness research appears to support this contention. Recent research has pointed to the importance of cognitive processes in mediating the development of learned helplessness, and further research and theory must focus on these cognitive aspects of learned helplessness.

It is apparent that learned helplessness has been conceptualized primarily as a *situational* paradigm; that is, researchers have focused on delineating the situational conditions that produce learned helplessness in a majority of subjects. In doing so, however, the literature has largely neglected the processes by which these situational experiences are translated into cognitive schemata, the characteristics of these schemata, and the processes by which cognitive schemata influence future behavior. It is our contention that the situational view of human behavior does not adequately represent or explain learned helplessness.

In view of the deficiencies in the present theory of learned helplessness noted above, the possible significance of the learned helplessness phenomenon, and the continued interest and research in this area, it seems appropriate at this time to propose a revised model of human learned helplessness. The model presented below attempts to outline a

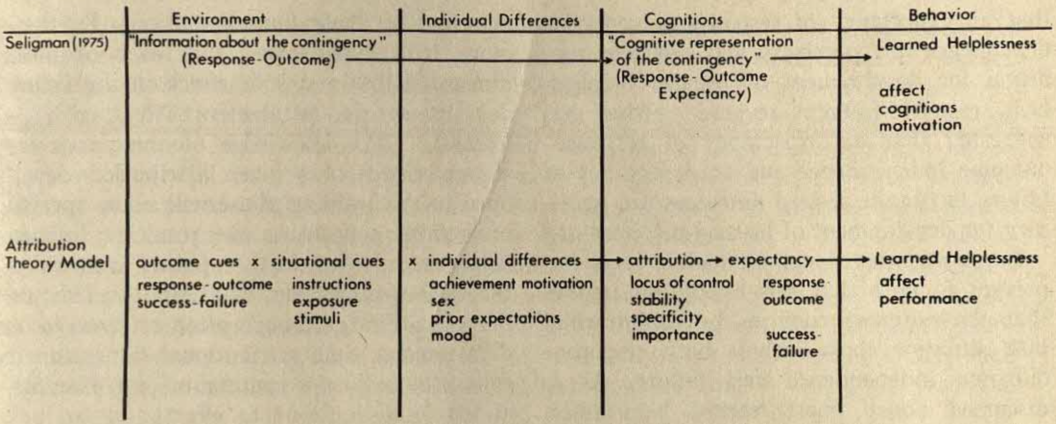

Figure 1. A comparison of theories of learned helplessness.

modified version of Seligman's theory of learned helplessness that better fits the available data and that gives definitive directions for new research in the area.

Attribution-Theory Model

Figure 1 presents the basic framework of both Seligman's model and the present revised model of learned helplessness. The present model differs from Seligman's model in several general areas. The first difference concerns the complexity of the antecedents of learned helplessness. Seligman (1975) postulated a single term of "information about the contingency" (p. 49), which refers to the environmental cues concerning response–outcome dependency, whereas the present model subdivides environmental events into two categories: outcome cues and situational cues. Outcome cues refer to the characteristics of the feedback concerning an individual's performance in a given situation, including Seligman's concern with response–outcome dependency. Situational cues refer to the stimuli present in the situation itself that influence the individual's perception and interpretation of outcomes. Additionally, the revised model includes an individual differences term and is explicitly interactional. Environmental events of outcomes and situational cues are hypothesized to interact with each other and with individual differences variables to influence the individual's cognitive processes. The final difference concerns the cognitive processes involved in learned helplessness. In addition to Seligman's expectancy term, the present model includes an attribution term.

In keeping with the previous focus on the five salient issues concerning learned helplessness, these variables and the present model are discussed below in more detail within the context of these issues.

Nature

In the present model, the nature of learned helplessness is presumed to be similar to that originally proposed by Seligman (1975). It differs from the earlier model by separating deficits resulting from learned helplessness into affective and performance components rather than into affective, motivational, and cognitive aspects. The binary distinction conforms more closely with current research, which has not successfully isolated cognitive and motivational deficits. The present model also differs from Seligman's position by suggesting that the affective and performance components of learned helplessness can occur independently and will vary with the content of the individual's attributions.

Etiology

The revised model makes two major additions to Seligman's theory concerning the etiology of learned helplessness. The first change concerns the content of expectancy that is hypothesized to produce learned helplessness. Although Seligman (1975) suggested

that an expectancy of response–outcome independence is a necessary and sufficient condition for development of learned helplessness, recent research, reviewed above, has suggested that an expectancy of response–outcome independence and an expectancy of failure to obtain desired outcomes are necessary for development of learned helplessness.[3]

From an operational viewpoint, it is important to note that this hypothesis implies that the outcome cues in the experimental task situation must include both response–outcome independence *and* failure. As is discussed above, most learned helplessness studies have used procedures that expose subjects to failure as well as noncontingent outcomes. In the remainder of this article, outcomes that are response independent and undesired are referred to as *learned helplessness outcomes.*

The second addition concerning etiology in the revised model is the inclusion of the attribution term, which is derived primarily from the theory and research of attribution theory (Weiner, 1974; Weiner et al., 1971). In contrast with the single expectancy term of Seligman's model, attribution theory suggests that analysis of the individual's ascriptions of causality of environmental events will lead to more accurate representations of cognitive processing and to better prediction of future behavior. Seligman suggested that exposure to environmental events leads to the development of an expectancy concerning control and that this expectancy in turn influences future behavior, whereas an attribution model suggests that the interaction of outcome and situational cues with individual differences variables results in an attribution to explain learned helplessness outcomes, and the characteristics of this cause then determine the expectancy that influences future behavior.

According to Weiner (1974), attributions can be characterized by two basic dimensions: locus of control (internal vs. external) and stability (stable vs. variable). The present model adds two additional dimensions that seem particularly relevant to learned helplessness: specificity (specific vs. general) and importance (important vs. unimportant). It is predicted that any attribution can be characterized by these four dimensions. Furthermore, it is hypothesized that each of these dimensions has a specific effect on the future development and parameters of learned helplessness. Thus, knowledge of the particular characteristics of a given attribution developed in the training phase will allow specific predictions concerning the resulting learned helplessness. Two further points concerning the various dimensions of attributions should be noted. First, although often referred to as dichotomous, each attributional dimension is conceptualized as a continuum; for example, although attributions to effort and to luck may be conceptualized as variable, luck may be more variable than effort. Second, each dimension of attribution is a subjective dimension; that is, one individual may perceive luck as more stable ("I'm a lucky person") than another ("That was just luck"). Thus, although general statements can be made concerning the dimensions of particular attributions, for best prediction the individual's perception of each dimension is necessary.

Locus of Control

The locus of control dimension represents a concern similar to the response–outcome contingency that Seligman postulated as basic to learned helplessness. However, the locus of control term used in this model does not represent the contingency of environmental events or an expectancy of response–outcome contingency but instead represents the assignment of causality for the perceived contingencies to internal or external sources. For example, in a typical learned helplessness study, subjects may perceive that their responses do not influence outcomes but may assign causality for this noncontingency to

---

[3] It should be noted that the present model treats task outcome and response–outcome contingency as orthogonal, independent dimensions. Although there is some evidence that these dimensions may not be independent (Jenkins & Ward, 1965), the relationship between outcome and contingency is complex and poorly understood at present (see Blaney, 1977). It seems prudent to treat these dimensions as independent and to use separate measures and predictions for each variable, until future research clarifies the relationship.

an internal source ("I am stupid") or an external source ("The experimenter is controlling the task"). Research in attribution theory (Eswara, 1972; Rest, Nierenberg, Weiner, & Heckhausen, 1973; Weiner & Kukla, 1970) has suggested that the attributional dimension of locus of control directly influences the subjects' affective reactions to task performance. These studies support the hypothesis that if one attributes failure to an internal cause, self-depreciation and negative affect result, whereas attribution of failure to an external cause minimizes this affect. Similarly, positive affects following success are maximized by attributions to internal causes and are minimized by attributions to external causes. These findings suggest that following exposure to learned helplessness outcomes, an attribution to an internal cause will produce negative affect, and an attribution to an external cause will reduce this negative affect.

Evidence for this hypothesis comes from the Roth and Kubal (1975) study, in which half the subjects were exposed to a manipulation designed to produce a belief that the learned helplessness training task was a measure of intelligence. This *important* group reported significantly more depression and frustration following training than did an *unimportant* group. If one assumes that task performance in the *important* condition was attributed to intellectual ability, an internal cause, then this study can be seen as supporting this hypothesis. Unfortunately, this study and others in the learned helplessness area have not focused on attributions and have not differentiated among the dimensions proposed in the present model. That is, although the Roth and Kubal manipulation can be hypothesized to produce an attribution to intellectual ability, no direct measures of attributions were taken, and furthermore, an attribution of intellectual ability can be characterized by other dimensions than locus of control, which may have influenced emotional responses. Thus, the Roth and Kubal study offers suggestive but nonconclusive support for the present model. Unfortunately, the presence of suggestive but nonconclusive evidence will be a common finding for most of the hypotheses of the model. The research focusing on the relationship of these dimensions of attributions to learned helplessness simply has not been done.

This hypothesis also offers an explanation for those studies that have reported an increase in self-reported anger and hostility following exposure to learned helplessness training conditions. As is discussed above, these results are not explained by Seligman's model. However, the attribution theory model suggests that an attribution of learned helplessness outcomes to an external source, such as experimenter control, would be predicted to reduce depression but also could be expected to increase the subject's anger at the external agent. Anecdotal evidence for this hypothesis comes from Miller and Seligman (1975, 1976), who stated that two subjects in each study reported high levels of anger after the training phase and told the experimenter that "they had decided early in the experiment that it had been rigged so that they could not escape the noise and that this had made them angry" (Miller & Seligman, 1975, p. 235). Moreover, these subjects reported large decreases in depression. This anecdotal evidence provides further support for the hypothesis that attributions mediate affective reactions to learned helplessness outcomes.

Stability

Stability refers to the relative permanence associated with an attribution. Environmental events can be attributed to causes that are stable or variable. For example, *intelligence* is a relatively stable attribution, whereas *effort* or *luck* are relatively variable. Attribution theory hypothesizes that stability of attribution determines the degree of influence that past outcomes exert on expectancies for performance in future situations. Several studies (Fontaine, 1974; McMahan, 1973; Weiner et al., 1976) have supported this hypothesis. Thus, if one attributes past outcomes to luck (a variable cause) then these outcomes will not influence one's expectancies in future situations, but if one attributes past outcomes to ability (a stable outcome) then one's expectancies for performance in future situations will shift in the

direction of the outcome. These results suggest that stability of attribution mediates the degree of influence that past outcomes exert on expectancies for performance in future situations, or the degree of cross-situational generalization.

In the learned helplessness situation, in which the outcome cues to be explained are those of response–outcome independence and failure, this hypothesis suggests that an attribution to a stable cause will result in a shift of the subjects' expectancies for future performance toward noncontingency and failure and, therefore, generalization to dissimilar situations. This hypothesis, then, goes right to the heart of the learned helplessness paradigm, suggesting that the stability of attribution predicts the situational generalization of learned helplessness. Thus, the next postulate of the model suggests that an attribution of learned helplessness outcomes to a stable cause will tend to increase the situational generalization of these outcomes.

This hypothesis concerning cross-situational generalization is supported by the Dweck and Reppucci (1973) study in which the greatest cross-situational generalization of learned helplessness deficits occurred in those children who attributed performance to ability, a stable cause, and children who showed the fewest deficits attributed their performance to effort, a variable cause. The results of Roth and Kubal (1975) and Tennen and Eller (1977) also lend support to this hypothesis. In these studies cross-situational generalization was found, but only in the experimental groups who had been exposed to an experimental manipulation designed to induce attributions to intellectual ability, a stable cause.

Specificity

Although attribution theory does not address itself to this dimension, attributions can also be characterized by their specificity or generalizability. In the learned helplessness paradigm, the specificity of attribution is postulated to predict the number of future tasks that will be affected by the expectancies developed in the training phase. For example, if a subject attributed learned helplessness outcomes to the ability to solve discrimination problems, a specific cause, then expectancies for and performance on future math problems should not be affected. But if the attribution were to a general cause, ability to solve problems, then expectancies for and performance on future math problems should be affected. Thus, the present model hypothesizes that attribution of learned helplessness outcomes to a general cause will tend to increase the influence of the training-phase outcomes on expectancies and performance in different types of tasks. Unfortunately, no study has directly investigated the effects of this dimension on learned helplessness.

Importance

The last dimension of attribution to be discussed is subjective importance, that is, the relative value a person assigns to an event. Subjective importance or reinforcement value has been discussed as a major component of the social-learning theory of human behavior (Rotter, 1954; Rotter, Chance, & Phares, 1972) but has not been discussed in detail by attribution theorists. In social-learning theory, the construct of subjective importance is seen as a major dimension of the task. The present model, however, in keeping with an emphasis on attributions, predicts that attributions, as well as tasks, differ in the degree of importance to a given individual and that the subjective importance of an attribution can also influence present and future behavior. This model further suggests that the influence of the dimension of subjective importance will be manifested primarily in terms of the magnitude of the affective and performance deficits predicted by the other dimensions of attributions.[4] Thus, it is hy-

[4] The subjective importance of the attribution is not the only factor that contributes to the magnitude of deficits. As social-learning theory and Abramson, Seligman, and Teasdale (1978) have mentioned, the subjective importance of the outcome itself can also influence magnitude. Similarly, the other dimensions of attributions will affect magnitude. Attributions to causes that are relatively stable or general will, due to their relative generalizability, increase the magnitude of learned helplessness deficits.

pothesized that the magnitude of learned helplessness deficits will covary with the subjective importance of the attribution of learned helplessness outcomes.

Two studies designed to vary subjective importance (Roth & Kubal, 1975; Miller & Gold, Note 3) have manipulated experimental task cues to increase the subjects' belief that task performance reflected intellectual ability. Although there are no direct data, this type of manipulation appears to increase the probability of an attribution to intellectual ability, presumably an important attribution for most college students. Roth and Kubal reported that subjects exposed to the noncontingent *important* manipulation reported increased depression and anxiety and increased performance deficits. Miller and Gold also reported significantly greater performance deficits in their noncontingent *important* condition. Of course, an attribution of intellectual ability can also be characterized as internal, stable, and general, so it is not clear that the importance of the attribution is *the* causal factor.

The basic etiological hypotheses of the revised model of learned helplessness have now been presented. Exposure to outcome cues of response–outcome independence and failure results in an attribution to explain these outcomes. The characteristics of the attributions constructed are predicted to determine the development, type, and generalization of learned helplessness deficits. The dimension of locus of control is predicted to determine the resulting affective components of learned helplessness, with an attribution of learned helplessness outcomes to an internal cause hypothesized to result in depression and anxiety. Stability of attribution is predicted to determine cross-situational generalization, with attributions to a stable cause resulting in cross-situational generalization of learned helplessness deficits. Specificity of attribution is hypothesized to control the cross-task generalization, with attributions to general causes resulting in cross-task generalization. The importance dimension is hypothesized to affect the intensity of the deficits produced in learned helplessness, with attributions to important causes resulting in maximum disability. Combining these hypotheses, it should be noted that attributions to causes that are internal, important, stable, and general are predicted to maximize the severity and generalization of learned helplessness, whereas attributions to causes that are external, unimportant, variable, and specific will minimize deficits.

As with other cognitive processes, the construction of attributions can be influenced by a variety of other factors. Thus, the next task of the model is to specify those situational cues that may interact with outcome cues and individual differences variables to affect the attributional process.

Situational Cues

As is mentioned above, situational cues refer to the stimuli present in the situation that exert influence on the subjects' attributions of task outcome. Several situational task cues have been identified in the learned helplessness literature, including (a) instructions regarding the contingency of responses and outcomes (Geer et al., 1970; Glass & Singer, 1972; Hiroto, 1974), (b) instructions regarding task difficulty (Klein et al., 1976), (c) instructions and other task cues specifying the nature of the task (Roth & Kubal, 1975; Miller & Gold, Note 3), and (d) the amount of exposure to learned helplessness conditions (Roth & Kubal, 1975). Other situational cues that are hypothesized by attribution theory to influence the development of attributions include social norms, observation of others' performance, and type of task (Weiner, 1974).

Space limitations prevent a discussion of the specific effects of all of these situational cues (see Weiner, 1974), but an example may prove helpful in understanding the significance of this class of variables. Klein et al. (1976) reported that instructions that the task was difficult tended to increase attributions of learned helplessness outcomes to task difficulty, an external, variable, and specific cause, whereas instructions that the task was easy tended to increase the probability of attributions to ability, an internal, stable, and general cause. These instructions also produced corresponding differences in task performance. Thus, it can be seen that

situational cues interact with outcome cues to produce an attribution that then influences expectancies for future performance and later task behavior.

Individual Differences Variables

Individual Differences Variables is perhaps a misnomer for this section, since a majority of the variables discussed are interactions between situational and individual differences variables. However, the purpose of this section is to specify those individual differences variables that may interact with situational variables to produce differential influences on learned helplessness performance. Since a number of individual differences variables have been found to influence the attributional process (see Weiner, 1974), this article presents only those variables specifically relevant to learned helplessness.

One individual differences variable that has been shown to influence attribution is gender. As is discussed above, Dweck and Reppucci (1973) reported different attributions from male and female children, with males tending to attribute failure outcomes to effort and females tending to attribute them to ability. These results suggest that females would tend to be more susceptible to learned helplessness manipulations. However, as another study (Dweck & Bush, 1976) reported, these results appear to be further mediated by the situational cue of the role of the evaluator (peer vs. adult). Clearly, then, sex is a potent variable that can influence attributions and development of learned helplessness. It is also clear that the interaction among sex, learned helplessness, and attributions is a complex one, with other variables playing a major role. These results also indicate that sex is one variable that should be controlled in future learned helplessness research.

Another individual differences variable that has been shown to influence the development of attribution is prior expectancies of future outcomes. Several studies have reported data that suggest that the congruency between prior expectancies and present outcomes can influence the attributional process. Feather (1969; Feather & Simon, 1971a, 1971b) assessed subjects' prior expectancies by subjects' reports (Feather, 1969) or previous experience (Feather & Simon, 1971a, 1971b). Subjects were then given anagram problems and were asked to rate the causes of performance outcomes. These results suggested that an outcome that is discrepant from previously held expectancies tends to be attributed to external causes, and outcomes congruent with expectancies tend to be attributed to internal causes. These results were replicated by Gilmor and Minton (1974). In a study investigating another dimension of attributions, McMahan (1973) also used the anagram problems and found that expectancy disconfirmation produced attributions to variable causes and that expectancy confirmation led to attributions to stable causes.

These results suggest that individuals tend to attribute discrepant outcomes to causes that lead to the smallest change in the individual's previously held expectancies. If this is true, then one would also predict that discrepant outcomes would be attributed to specific causes rather than to general causes. Unfortunately, there has been no reported research bearing directly on this question. However, the available research does suggest that when learned helplessness outcomes are highly discrepant from previously held expectancies, attributions tend to be made to external, variable, and specific causes. Conversely, if learned helplessness outcomes are congruent with previously held expectancies, attributions tend toward internal, stable, and general causes. Thus, learned helplessness is predicted to be more likely to occur when training-task outcomes are congruent with prior expectancies than when outcomes are incongruent. This prediction is supported by Hiroto's (1974) study, in which subjects with prior expectancies of an external locus of control (noncontingent) showed greater deficits following exposure to a noncontingent failure experience than did subjects with a belief in an internal locus of control.

A final important individual differences variable for the learned helplessness paradigm is depression. Since learned helplessness has been advanced as a theory of depression, the interaction between depressed mood and exposure to learned helplessness outcomes

should be explored in some detail. Depressed subjects have been shown to be generally more pessimistic about future outcomes than are nondepressed subjects (Beck, 1974; Loeb, Beck, & Diggory, 1971)[5] and to expect the independence of responses and outcomes (Calhoun, Cheney, & Dawes, 1974). Since learned helplessness outcomes of noncontingency and failure are congruent with these expectations of depressed subjects, the present model suggests that depressed subjects would tend to attribute learned helplessness outcomes to causes that are internal, stable, and general. Current research has generally supported this prediction. Klein et al. (1976) reported that depressed subjects tended to attribute performance to ability, an internal, stable, and general cause, after failure but not after success. Similarly, Miller and Seligman (1973) reported that depressed subjects tended to show smaller expectancy changes than did nondepressed subjects on a skill task after failure, but there was no difference after success. Since a small expectancy change has been shown to be associated with a stable attribution (Weiner et al., 1976), Miller and Seligman's results suggest that depressed subjects tend to attribute noncontingent failure on skill tasks to stable causes.

If depressed subjects tend to attribute learned helplessness outcomes to internal, stable, and general causes, then the present model predicts that depressed subjects would exhibit greater performance deficits and greater affective reactions than would nondepressed subjects, following exposure to learned helplessness outcomes. Two studies (Hammen & Krantz, 1976; Wener & Rehm, 1975) offer unambiguous support for this hypothesis. In both studies, depressed and nondepressed subjects were exposed to noncontingent success and failure outcomes. Following failure, depressed subjects' responses showed more depression, less self-confidence, and decreased expectancies for future success. No difference between groups was reported with success outcomes. Although these results support the hypothesis of this model, they appear inconsistent with the learned helplessness studies of Miller and Seligman (1975, 1976), which reported that depressed subjects exposed to learned helplessness training do not differ from depressed subjects without learned helplessness exposure. However, as is discussed above, Miller and Seligman (1975, 1976) reported that in both studies, two of eight depressed subjects exhibited performance similar to that of nondepressed/no learned helplessness subjects on the test task. The present view is that these four subjects may have attributed learned helplessness outcomes to experimenter control, an external, variable, and specific cause. Thus, for these depressed subjects, although learned helplessness outcomes may have been congruent with their prior expectancies, other situational cues may have led to attributions of experimenter control, which in turn may have led to nondepressed performance and therefore to a reduction in the difference between the depressed/learned helplessness group and the depressed/no-treatment group. Miller and Seligman (1976) reported that the remaining depressed/learned helplessness subjects did show greater performance deficits than the depressed/no-treatment group, but these differences were not statistically significant. They further suggested the possible operation of a floor effect not found in the Hammen and Krantz (1976) or Wener and Rehm (1975) studies. These data, though somewhat ambiguous, tend to support the present hypothesis, that depressed subjects tend to attribute outcomes of noncontingency and failure to internal, stable, and general causes and therefore tend to exhibit greater depression and performance deficits.

This hypothesis, in combination with the basic etiological hypotheses of the model, suggests the following chronology of reactive depression: Due to some combination of situational cues and repeated exposure to noncontingent and nondesired outcomes, the individual's attributions of these outcomes

---

[5] Miller and Seligman (1973) and Hammen and Krantz (1976) have reported that depressed subjects do not differ from nondepressed ones in initial task expectancies. These studies, however, only used nonclinically depressed subjects and assessed only specific task expectancy. The lowered expectancy discussed above reflects a more generalized expectancy, which is probably more pronounced in clinically depressed populations.

changes from external, variable, and specific causes to internal, stable, and general causes. This change results in a change in future expectancies, performance, and mood. Thus, in new situations, the individual expects noncontingency and failure, and when these congruent outcomes occur, they are attributed to internal, stable, and general causes, whereas discrepant outcomes of success and contingency are attributed to external, variable, and specific causes and do not influence future expectancies, performance, or mood. The individual is then depressed and tends to disregard outcomes of success and contingency while overgeneralizing failure and noncontingent outcomes. Thus, response initiation declines, a greater number of failure and noncontingent outcomes do occur, and the vicious circle of depression has begun.

Generalization

As is reported above, the lack of cross-situational generalization is a major obstacle to the significance of the learned helplessness paradigm. Seligman's theory offers no convincing explanation for the lack of results. As is suggested above, in the Etiology section, the present revised model hypothesizes that cross-situational generalization of learned helplessness is a function of the stability dimension of the attributions constructed. According to this hypothesis, cross-situational generalization should result if and when attributions of learned helplessness outcomes are made to relatively stable causes and should not result when attributions are made to relatively variable causes.

However, performance deficits in a situationally similar task may be due to attributions that are relatively variable but that are stable for the duration of the experiment, such as experimenter control or task difficulty, or such deficits may be due to relatively stable causes such as ability or personality. The present model suggests that performance deficits that occur as a result of attributions to relatively variable causes are really "pseudohelplessness" because they do not represent a change in the individual's basic expectancies or mode of adaptation. Deficits that occur as a result of attributions to stable causes do result in more lasting, generalized learned helplessness.

Awareness of the role of stability of attributions in the generalization of learned helplessness leads to several other hypotheses and explanations concerning generalization of learned helplessness. First, since the typical nondepressed college student tends to expect response–outcome dependence and success (Parducci, 1963, 1965, 1968), the outcomes of the learned helplessness training phase will be highly discrepant and thus are predicted to be attributed to causes that are relatively variable. Since attributions to variable causes are not predicted to result in cross-situational generalization of deficits, the present model predicts that studies using nondepressed college students would produce temporary, specific pseudohelplessness deficits during the experimental task situation, but not the relatively permanent, generalizable learned helplessness described by Seligman, unless very strong situational cues designed to produce more stable attributions were utilized. One of the few studies to report cross-situational generalization used such situational cues. Roth and Kubal (1975) used three situational manipulations, each of which would tend to increase the probability of an attribution to a stable cause and thus to cross-situational generalization of learned helplessness.

This interpretation of the learned helplessness research is crucial to future research in the area because (a) it explains the current lack of documented cross-situational generalization, and (b) it suggests that to produce generalized learned helplessness, the experimental situational cues will have to be manipulated to induce attributions to relatively stable causes.

Alleviation

The final statement of the present model concerns alleviation or treatment of learned helplessness. Following the basic statement of the model, treatment of learned helplessness is focused on changing the subjects' attributions. The first step in treating learned helplessness is assessing the type of learned helplessness involved. Are the obtained defi-

cits due to the pseudohelplessness produced by an attribution to external, variable, and specific causes, or are deficits due to learned helplessness produced by internal, stable, and general attributions? If the deficits are due to pseudohelplessness, then a change in outcomes or situations would be sufficient to change future expectancies and performance. That is, if one attributed learned helplessness outcomes of response–outcome independence and failure to a variable or specific cause, then a change in these outcomes will be sufficient to change expectancies for future outcomes. This reasoning suggests that for pseudohelplessness, exposure to experiences of response–outcome dependence and success will alleviate deficits. The success of this treatment with nondepressed subjects has been demonstrated by Klein and Seligman (1976) and Kilpatrick-Tabak and Roth (Note 4).

On the other hand, if deficits are due to learned helplessness or depression caused by an attribution of learned helplessness outcomes to internal, stable, and general causes, then exposure to response-dependent success will be attributed to variable and specific causes and will not influence future expectancies of performance. The failure of exposure to response-dependent success to alleviate in depressed subjects was demonstrated by Kilpatrick-Tabak and Roth (Note 4). According to the present model, treatment of learned helplessness or depression would require a direct focus on changing the attributions themselves. Examples of these changes and the effectiveness of this type of treatment can be seen in the studies of Klein et al. (1976) and Dweck (1975).

The revised formulation of learned helplessness has now been presented. The interaction of situational cues, outcome cues, and individual differences was hypothesized to result in an attribution to explain learned helplessness outcomes. The characteristics of this attribution were postulated to mediate the influence of learned helplessness outcomes on expectancies and behavior in future situations. Four dimensions of attributions were discussed: (a) locus of control, (b) stability, (c) specificity, and (d) importance. Attributions characterized as internal, stable, general, and important were predicted to maximize learned helplessness.

This model appears to offer a more accurate and predictive theory of learned helplessness. We hope that the model will open new avenues of research within the learned helplessness paradigm. Beyond testing the specific hypotheses of the model itself, the focus on cognitive processes and attributions may lead to an increased awareness of the complexity of human cognition and the inclusion of measures of cognition in experimental designs. Also, the present model can serve as a springboard for investigation of interactions of outcome and situational cues with individual differences variables and of the relations of these interactions with cognitive processes and future behavior.

The Concepts of Alienation and Involvement Revisited

Rabindra N. Kanungo
Faculty of Management, McGill University, Montreal, Canada

In an attempt to clarify and operationalize the concepts of alienation and involvement, this article critically examines several current sociological and psychological approaches to the concepts. Several common sources of confusion surrounding the treatment of the concepts are identified. A motivational formulation of the concepts is suggested to achieve greater parsimony and integration of the diverse sociological and psychological thinking on the issue. Finally, some major implications of this motivational formulation for future empirical studies on alienation and involvement at work and in other situations are indicated.

In the social science literature of the past two decades, one encounters very often the usage of the concept *alienation* and its obverse, *involvement* (Johnson, 1973). These concepts have been used by sociologists, psychologists, political scientists, theologians, philosophers, and historians to describe and explain various contemporary social phenomena. In fact, the terms alienation and involvement have been used so often and in so many contexts that they have acquired an aura of equivocality. As Seeman (1971) pointed out, the concept of alienation has been "popularly adopted as the signature of the present epoch. It has become routine to define our troubles in the language of alienation and to seek solutions in those terms. But signatures are sometimes hard to read, sometimes spurious, and sometimes too casually and promiscuously used. They ought to be examined with care" (p. 135). Similar concern was expressed by Johnson (1973), who characterized the concept of alienation as being capable of carrying a great deal of feeling "in an inexplicit, perplexing and deeply annoying way" (p. 28). Although in recent years many psychologists and sociologists have attempted to demystify and to operationalize the concept (Lawler & Hall, 1970; Lodahl & Kejner, 1965; Saleh & Hosek, 1976; Seeman, 1971; Vroom, 1962), none of them seem to offer a scientifically organized and meaningful view of the concept that could have broad generality across cultures. Although most of the researchers have tried to explain the phenomena of alienation and involvement in social psychological terms (Clark, 1959; Lawler & Hall, 1970; Seeman, 1959), the language they have used seems to have created more confusion than clarity. Sociological and psychological explanations of the phenomena seem to run parallel courses of their own without any serious attempt at integration. In fact, if one puts together the various explanations of the phenomena advanced by these writers, one ends up with greater conceptual fuzziness rather than clarity or understanding. If we take seriously Seeman's (1971) call for a careful examination of the concept for better clarity and rigor, we ought to seek a reformulation of the issue. The present article is an effort in this direction.

First, the article traces the manifold nature of the concept of alienation as it has been viewed by several researchers in this area. Second, the article identifies the major sources of confusion surrounding this concept. And finally, the article presents a motivational formulation of alienation and a comprehen-

The author wishes to thank George Strauss and Thomas Reynolds of the University of California, Berkeley and Gerald Gorn of McGill University for their helpful comments on an earlier draft of the article.

sive conceptual framework that could be used in future research. Such a framework is aimed at integrating the sociological and the psychological thinking on the issue and at providing a more complete understanding of the complex phenomena of alienation and involvement in a parsimonious way. It must be pointed out that the terms *alienation* and *involvement* are used here to indicate bipolar states of the same phenomena. Furthermore, since the phenomena have been studied empirically mostly in work situations, I have chosen to discuss specifically the nature of alienation and involvement at work in some detail. This choice however does not imply that one should limit the use of the concepts of alienation or involvement to work situations alone. The framework suggested in this article is in fact intended to be used by researchers not only to study work alienation phenomena but also to study alienation in family life, in religious contexts, and for that matter in any other specific aspects of one's environment.

Alienation and Involvement: Some Earlier Formulations

Although contemporary social scientists often consider the state of alienation in individuals as distinctly a postindustrial phenomenon, theologians and philosophers claim otherwise. As Johnson (1973) pointed out, social alienation as an observed phenomenon is quite ancient and the term alienation is an antique one. Theologians take the credit for using the term as an explanatory concept. Alienation, according to them, refers to states of separation of human beings from God, from their own bodies, from their fellow human beings, and from their institutions. This interpretation is clearly reflected in the use of dualism of body and soul in theological writings. Essentially, the theologians observed and explained the meaninglessness of human existence in terms of spiritual alienation or separation from God and moral principles. Although alienation as a psychological state of the individual (or as a collective social phenomenon) has been recognized for centuries, the scientific treatment of the concept with regard to its nature and its effect was attempted first by empirically oriented sociologists and then, more recently, by social psychologists. Thus the concept has lived through two distinct traditions, the rational and the empirical. The rational tradition of the concept comes largely from the writings of theologians (Macquarrie, 1973) and philosophers (Denise, 1973). The empirical tradition results from the recent works of sociologists and psychologists. The main focus of the present article is a critical review of the empirical tradition.

In dealing with states of alienation in the spiritual life of individuals, theological approaches emphasized the idea that there can be alienation of different sorts depending on what elements of one's environment one is separated from (such as God, one's own body, other people, etc.). Following a similar line of reasoning, the social scientists of today talk of different kinds of alienation such as job alienation, organizational alienation, urban alienation, family alienation, and so on. From the point of view of conducting empirical research, social scientists consider the study of alienation in relation to single, well-defined environmental elements (such as job, family, etc.) to be more fruitful than the study of alienation in a global sense (Clark, 1959; Seeman, 1971). The theological and philosophical approaches to the concept influenced the thinking of modern social scientists in yet another way. The more recent writers have identified the core meaning of the concept of alienation as a dissociative state of the individual (a cognitive sense of separation) in relation to some other element in his or her environment (Schacht, 1970). In the following section, an overview of the sociological and the psychological approaches to the concept is presented.

The Sociological Approach

The contributions of sociologists in explaining the nature of alienation have been the most extensive. In the classics of sociology, such as in the writings of Marx, Weber, and Durkheim, the concept of alienation received very comprehensive treatment. Al-

though Rousseau was the first to provide sociological treatment of the concept, it was Marx and later Weber who put the concept on firmer analytic ground. The evidence of their powerful influence still persists in the works of contemporary sociologists (Seeman, 1959, 1971).

If theologians identified the basic psychological state of alienation in men in their spiritual lives, Marx identified it in their material, working lives. According to Marx (1844/1932), labor or working on a job is the "existential activity of man, his free conscious activity—not a means of maintaining his life but for developing his universal nature" (pp. 87–88). Thus, ideally a state of work involvement can result when the work situation elicits job behavior that is perceived to be (a) voluntary, (b) not instrumental in satisfying basic physical needs, (c) instrumental in satisfying Maslow-type (1954) higher order needs such as the need for self-realization or self-actualization, and (d) conducive to developing individuals' abilities to their fullest potential. In the absence of such perceptions, the individual worker is bound to experience a state of alienation from work. Most work setups according to Marx provide conditions that alienate workers rather than involve them. Marx identified two major job conditions that are responsible for alienation among workers. They are (a) separation of workers from the products of their labor and (b) separation of workers from the means of production. The first job condition implies that the product is perceived as not belonging to the worker. The worker also perceives that he or she cannot influence the disposition or quality of the product. Thus he or she lacks a sense of ownership and of control over the product and its quality. The second job condition implies that the worker perceives a lack of control over the function of the machines and other means of production. Finding that he or she has no control over working life, the worker is bound to be estranged or to separate working life from the rest of his or her existence over which Marx assumes the worker has complete control.

From the preceding discussion, it becomes obvious that it is the lack of *autonomy* and *control* of one's behavior and its effects that defines the Marxian concept of alienation. If one translates the alienation state of the worker into motivational terms, it becomes quite clear that Marx intended to measure alienation in terms of the satisfaction of a single set of needs, the ego needs for independence, achievement, and power. In the Marxian formulation, the role of other human needs, such as the physical and the social ones, has been completely disregarded, as if the needs do not constitute a part of one's self or perhaps constitute a very insignificant part exerting almost no influence in causing states of alienation. This interpretation of the Marxian formulation may appear oversimplified, but it is clearly reflected in the following quotation from Marx (1844/1932):

> What constitutes alienation of labor? First, that work is *external* to the worker, that it is not part of his nature; and that, consequently, he does not fulfill himself in his work but denies himself, has a feeling of misery rather than well-being, does not develop freely his mental and physical energies but is physically exhausted and mentally debased. The worker therefore feels himself at home only during his leisure time, whereas at work he feels homeless. His work is not voluntary but imposed, forced labor. It is not the satisfaction of a need, but only a means for satisfying other needs. (pp. 85–86)

One may notice the assumptions Marx makes while defining the state of alienation. Clearly he emphasizes the worker's experience of frustration of his or her autonomy and control needs at work, and whenever these needs are frustrated, Marx considers work to be external to the worker's self.

Another assumption made by Marx in the quotation relates to the instrumental and consummatory properties of job behavior. According to Marx, job behavior can be either instrumental activity that satisfies basic physical human needs or it can be consummatory activity. In the former sense job behavior is viewed as means to an end (satisfaction of extrinsic needs), and in the latter sense it is viewed as an end in itself. Theories of human motivation suggest that human behavior is purposive; it has directionality; it is initiated by need states; and it is always instrumental in satisfying these need states. An individual's job behavior is also purposive; it is aimed at

satisfying both the extrinsic and intrinsic need states (Lawler, 1973) of the individual. However, when Marx wrote of job behavior as an end in itself (reflecting a state of involvement), he did not recognize that such behavior is also instrumental in satisfying a set of intrinsic human needs.

Weber's treatment of the concept of alienation is very similar to that of Marx. As Gerth and Mills (1946) put it, "Marx's emphasis upon the wage worker as being 'separated' from the means of production becomes, in Weber's perspective, merely one special case of a universal trend. The modern soldier is equally 'separated' from the means of violence, the scientist from the means of enquiry, and the civil servant from the means of administration" (p. 50). Weber's exposure to the American way of life (political democracy and economic capitalism) and his study of the Protestant religion convinced him that the spirit of the Protestant work ethic is the key to the realization of man's potentialities to the fullest extent. As Gerth and Mills wrote, Weber was impressed by the "grandiose efficiency of a type of man, bred by free associations in which the individual had to prove himself before his equals, where no authoritative commands, but autonomous decisions, good sense, and responsible conduct train for citizenship" (p. 18). Such is the image Weber had of an involved worker. Like Marx, Weber also placed emphasis on the freedom to make one's own decisions, on assuming personal responsibility, and on proving one's worth through achievement at work. Translated into motivational terms, this implies that if the work setup cannot provide an environment that satisfies the needs for individual autonomy, responsibility, and achievement, it will create a state of alienation in the worker.

Unlike Marx and Weber, who viewed alienation as resulting primarily from perceived lack of freedom and control at work, Emile Durkheim, the French sociologist, saw it as a consequence of a condition of *anomie*, or the perceived lack of socially approved means and norms to guide one's behavior for the purpose of achieving culturally prescribed goals (Blauner, 1964; Durkheim, 1893; Shepard, 1971). The condition of anomie is often considered a postindustrial phenomenon. As Blauner (1964) observed, industrialization and urbanization of modern society have "destroyed the normative structure of a more traditional society and up-rooted people from the local groups and institutions which had provided stability and security" (p. 24). No longer being able to feel a sense of security and belonging, modern men and women find themselves isolated from others. This form of social alienation often results in normlessness and in its collective form manifests itself in various forms of urban unrest. In social psychological terms, this variant of alienation seems to stem from the frustration of social and security needs, the need to belong to groups for social approval and social comparison (Festinger, 1954; Maslow, 1954). The social psychological processes that explain how this form of alienation comes about are discussed later in the article.

The strong impact of Marx, Weber, and Durkheim is quite evident in contemporary sociological writings on the subject of alienation and involvement. For instance, Dubin (1956) defined involvement as *central life interest*. According to him, a job-involved person is one who considers work to be the most important part of his or her life and engages in it as an end in itself. A job-alienated person, on the other hand, engages in work in a purely instrumental fashion and perceives work as providing financial resources for more important off-the-job activities. Faunce (Note 1) also considered job involvement as a commitment to a job in which successful performance is regarded as an end in itself rather than as a means to some other end. For both Dubin and Faunce, the concepts of involvement and alienation are intimately related to the Protestant work ethic, the moral value of work, and personal responsibility as conceived by Weber.

In an attempt to clarify the concept of alienation, Seeman (1959, 1971) has proposed five different variants of the concept: powerlessness, meaninglessness, normlessness, isolation, and self-estrangement. According to Seeman, each variant refers to a different subjectively felt psychological state of the individual, caused by different environmental con-

ditions. Several other researchers, particularly Blauner (1964) and Shepard (1971), have used Seeman's classification and have tried to provide operational measures of the different categories of alienation at work. They also have suggested the antecedent physical and social conditions that produce each state of alienation.

Alienation in the form of *powerlessness* in the most general sense refers to a perceived lack of control over important events that affect one's life. Seeman (1959) used this variant of alienation to explain and describe men and women's alienation from the larger social order. An individual's inability to control and influence political systems, industrial economies, or international affairs may create a sense of powerlessness in him or her. Alienation in the sense of powerlessness also has been observed in job situations. For instance, Shepard (1971) described powerlessness at work as "the perceived lack of freedom and control on the job" (pp. 13–14). Blauner (1964) expressed similar views when he stated that "the non-alienated pole of the powerlessness dimension is freedom and control" (p. 16). According to Blauner, the powerlessness variant of alienation at work results from the mechanization process that controls the pace of work and thus limits workers' free movements. If one analyzes the sociological concept of powerlessness in motivational terms, it becomes obvious that if a situation constantly frustrates an individual's needs for autonomy and control, it will create in him or her a state of alienation of this type.

The second type of alienation is identified as a cognitive state of *meaninglessness* in the individual. In such a state, the individual is unable to predict social situations and the outcomes of his or her own and others' behavior. In the work setup such a state results from increasing specialization and division of labor. When the work process is broken down into simple minuscule tasks, and when such simple tasks involve no real responsibility and decision making, the work situation robs the worker of any sense of purpose. The job becomes meaningless for the worker. Meaninglessness of work may also result when the worker is not able to see the relation of his or her work to the total system of goals of the organization (Blauner, 1964; Shepard, 1971). Translated into motivational terms, this implies that continued frustration of an individual's needs for assuming personal responsibility and for gaining greater competence on the job (by being more knowledgeable about the environment for the sake of influencing it) causes this type of alienation. It may be noted that both the powerlessness and the meaninglessness interpretations of work alienation bear the mark of the Marxian belief that lack of control and freedom over the work process is the main cause of alienation.

The two other forms of alienation suggested by Seeman (1959) have their roots in Durkheim's (1893) description of anomie. Anomie refers to the perceived conditions of one's social environment, such as the perception of a breakdown of social norms regulating individual conduct in modern societies. The two forms of alienation that result from such perceived conditions of one's social environment are *normlessness* and *isolation.* An individual may develop a sense of normlessness when he or she finds that previously approved social norms are no longer effective in guiding behavior for the attainment of personal goals. In other words, the individual finds that to achieve given goals it is necessary to use socially unapproved behavior. Finding that he or she can no longer share the normative system because of its ineffectiveness, the person may develop norms of his or her own to guide behavior. Because his or her norms are different from those of others, the individual may eventually perceive himself or herself as being separate from society and its normative system. The dissociation of oneself from others results in the perception of social isolation. The dissociation of oneself from social norms results in normlessness or cultural estrangement. Alienation in the sense of social isolation and cultural estrangement refers to the perceived states of loneliness and rootlessness respectively (Seeman, 1971). It may be noticed that these two variants of alienation are related because they stem from the same basic condition of anomie.

States of loneliness and rootlessness have also been identified in work environments.

Blauner (1964), for instance, suggested that these forms of social alienation may be manifested on the job due to the lack of social integration of the worker. When an organization does not provide the worker any opportunity for developing a sense of membership or belonging in the social system, the worker is bound to show a sense of isolation from the system and its goals. From a motivational point of view, the two variants of social alienation, isolation and normlessness, seem to be based on two different social needs of the individual. Continuous frustration of the membership or belonging need of the individual may be the crucial determinant of the isolation form of alienation. The normlessness form of alienation, however, is determined by continuous frustration of another social need, the need to evaluate oneself through social comparison (Festinger, 1954). In the context of social influence theories, social psychologists (Jones & Gerard, 1967) have postulated two major kinds of influences that groups exert on the individual. They are referred to as the normative and the informational social influences. By being a member of the group and by adhering to the group norms, the individual fulfills his or her need to belong, to love, and to be loved by others. When, however, the group norms are perceived to be too restrictive and in conflict with the individual's personal goals, they cease to influence the individual. The group loses its normative influence on the individual. The person becomes an isolate in relation to the group. He or she perceives himself or herself as one who no longer belongs to the group and no longer is loved by others in the group. Such a psychological state can be identified as the isolation form of alienation. The individual also depends on the group norms for self-evaluation and for evaluating his or her abilities and opinions (Festinger, 1954). Group norms generally provide the person with information on how to behave, on what is right and what is wrong. When the individual finds that group norms do not provide useful information for self-evaluation, he or she may separate himself or herself from these norms and experience a state of normlessness. Thus, in terms of social influence theory, the two variants of social alienation result from the failure of the groups to exercise the two forms of social influence, normative and informational.

The final variant of alienation proposed by sociologists is *self-estrangement*. In many ways the characterization of this category of alienation has posed problems for sociological thinkers. Seeman (1971) admits that it is an "elusive idea" (p. 136), but then goes on to operationalize it. According to Seeman, a person is self-estranged when he or she is engaged in activity that is not rewarding in itself, but is instrumental (a means to an end) in satisfying extrinsic needs such as the needs for money, security, and so on. Following Seeman (1959), Shepard (1971) considers instrumental work orientation, or the degree to which one works for extrinsic-need satisfaction, to be an index of the self-estrangement kind of alienation in the work setup. Blauner (1964) suggests that a job encourages self-estrangement if it does not provide opportunity for expressing "unique abilities, potentialities, or personality of the worker" (p. 26). In motivational terms, Blauner's observation means that whenever the individual finds his or her environment (job or otherwise) lacking in opportunities for the satisfaction of self-actualization needs (Maslow, 1954) through expression of his or her potentialities, he or she experiences a state of self-estrangement. Following Marx, many contemporary sociologists believe that self-estrangement is the heart of the alienation concept, as if all other forms of alienation eventually result in self-estrangement. Blauner (1964) attests to this belief in the following remark: "When work activity does not permit control [powerlessness], evoke a sense of purpose [meaninglessness], or encourage larger identification [isolation], employment becomes simply a means to the end of making a living" (p. 3).

Characteristics of the Sociological Approach

At this point it may be helpful to identify some dominant considerations that have guided most sociological treatments of the concept of alienation.

First, one notices a stronger emphasis in sociological writings on the analysis and

measurement of the state of alienation than on the analysis and measurement of the state of involvement. In a sense, sociologists have focused their attention on the negative side of the issue with a clinical perspective on social systems. Thus, they have been more concerned with the diagnosis of states of alienation in social systems and consequent social maladies than with the identification of conditions for social involvement and growth. Like Freudian psychologists who attempt to explain human nature through an analysis of pathological psychological states, sociologists, taking the lead from Marx, have emphasized the analysis of alienation and resulting pathological states to explain the nature of social systems. In the same way as the Freudian influence in psychology delayed the formulation of growth theories of personality and motivation (Maslow, 1954; Allport, 1961), the Marxian influence in sociology may have retarded the progress of sociological theories in understanding better the nature of healthy and growing social systems. As is discussed later, unlike the sociological approaches outlined above, the current psychological approaches to the issue are trying to attack the problem from the positive side through the study of the concept of involvement.

The second consideration that has dominated various sociological treatments of alienation is their emphasis on studying alienation in groups and social systems. The level of analysis of the concept in most sociological approaches has been at the social system level rather than at the individual level. This has created measurement problems. Although sociologists often talk of the frequency of volatile activism, of suicide rates, of crime rates, and so on as indices of alienation in social systems, they find it hard to establish and theoretically justify the validity and the reliability of these measures. The records on such social maladies are notoriously unreliable. Very often incidents of activism, crime, and suicide go unreported. Even if the incidents are recorded accurately, it is often difficult to infer from these data states of alienation in individual persons. For instance, an activist in his or her desire to bring about changes in the social system may be showing signs of greater involvement in the social system than would an apathetic conformist.

Third, sociological approaches generally describe the state of alienation not in specific behavioral terms, but in terms of epiphenomenal categories. As Johnson (1973) pointed out, alienation is seen as *"an epiphenomenal abstraction,* collectively summarizing a series of specific behaviors and categorizing them as 'loneliness,' 'normlessness,' 'isolation,' etc." (p. 40). Such epiphenomenal descriptions of the concept may have the flavor of intellectual romanticism, but have very little scientific value because they pose problems of empirical verification. The concept of alienation as an epiphenomenal abstraction tends to carry excess meaning and therefore eludes precise measurement. Besides, such an abstraction merely describes alienation; it does not explain it.

Finally, most sociological approaches consider the presence of individual autonomy, control, and power over the environment as basic preconditions for removing the state of alienation.

The Psychological Approach

The psychological approach to the concept of alienation has been somewhat sketchy compared to the sociological approach described earlier. In psychological literature, the treatment of the concept does not have as long and as rich a tradition as in sociology. The interest in the concept is very recent among psychologists, and they have essentially taken an empirical (and exploratory) approach to the study of the problem. Development of psychological theories to explain the phenomenon of alienation is simply absent from the literature. Furthermore, in contrast to the sociological approach, psychologists have attempted to analyze the nature of alienation only in the limited context of job situations. Unlike sociologists, psychologists have studied the problem of alienation from the point of view of job involvement and have attempted to define and measure involvement at work rather than alienation at work.

In trying to explain the nature of job involvement, psychologists have concentrated

on the analysis of specific motivational states of the individual in work situations. Psychological explanations are based on motivation theories and therefore tend to emphasize the need-satisfying qualities of the job as basic determinants of job involvement. For instance, Vroom (1962) proposed that a person's attempts to satisfy his or her needs for self-esteem through work on the job lead to job involvement. In his study, "The degree of job involvement for a particular person was measured by his choice of 'ego' rather than extrinsic factors in describing the sources of satisfaction and dissatisfaction on the job" (p. 161). Vroom seems to emphasize intrinsic-need satisfaction as the essential condition for higher job involvement. In his view, higher autonomy extended to the individual results in higher ego involvement, which in turn leads to a higher level of job performance.

Lodahl and Kejner (1965) proposed two definitions of job involvement. One of their definitions states that "job involvement is the degree to which a person is identified psychologically with his work, or the importance of work in his total self-image" (p. 24). Such a psychological state of identification with work may result partly from early socialization training during which the individual may internalize the value of the goodness of work. Lodahl and Kejner (1965) recognized this possibility. They stated that the concept of job involvement "operationalizes the 'protestant ethic' and because it is a result of the introjection of certain values about work into the self, it is probably resistant to changes in the person due to the nature of a particular job" (p. 25). Lodahl and Kejner also provided another definition of job involvement; this definition states that job involvement is "the degree to which a person's work performance affects his self-esteem" (p. 25). These two definitions are quite distinct, and Lodahl and Kejner made no attempt in their study to show how the two are related. In fact, the questionnaire measure of job involvement they developed includes items reflecting both definitions. Use of their questionnaire measure in job involvement research therefore provides data that are hard to interpret.

Recently Rabinowitz and Hall (1977) critically reviewed the work of several researchers who have made use of the definitions of job involvement mentioned above. Their review clearly suggests that there is a great deal of confusion and ambiguity in theories about job involvement. Furthermore, as these authors pointed out, "The confusion does not stop at the theoretical level, but rather continues in the empirical studies of involvement" (p. 267).

Weissenberg and Gruenfeld (1968) investigated the relationship between satisfaction with various job factors and job involvement. They concluded that increased job involvement is positively related to satisfaction with motivators or job-content factors (Herzberg, 1966) such as achievement, responsibility, independence, and so forth. These motivators tend to satisfy the intrinsic needs of the individual. The extrinsic needs, however, are satisfied through job-context factors such as company policies, nature of supervision, salary, benefits, and working conditions. According to these researchers, satisfaction with the job-context factors is unrelated to job involvement, but the latter can be predicted from the satisfaction with the motivators in the job.

Lawler and Hall (1970) for the first time distinguished the psychological state of job involvement from two other psychological states of the worker. According to Lawler and Hall, job involvement is different from both intrinsic motivation on the job and job satisfaction. Intrinsic motivation refers to a state of the individual in which satisfaction of the intrinsic needs is contingent upon appropriate job behavior and in which job satisfaction results from satisfaction of the needs of the individual through the attainment of job outcomes without any regard to the contingencies of the outcomes. Lawler and Hall argue in favor of the definition of job involvement suggested by Lodahl and Kejner (1965): Job involvement is seen in terms of psychological identification with work or the importance of work to one's total self-image. In general Lawler and Hall suggest that job involvement refers to the "degree to which a person's total work situation is an important part of his life. The job-involved person is

one who is affected very much personally by his whole job situation, presumably because he perceives his job as an important part of his self-concept and perhaps as a place to satisfy his important needs (e.g., his need for self-esteem)" (pp. 310–311). It appears that in defining the concept of involvement, Lawler and Hall assumed that intrinsic or growth needs (Alderfer, 1972) are central to the self-concept of the individual. To emphasize the centrality of intrinsic needs, they pointed out that "the more the job is seen to allow the holder to influence what goes on, to be creative, and to use his skills and abilities, the more involved he will be in the job" (p. 310). In the same article, Lawler and Hall (1970) reiterated their position with the following remark: "Other things being equal, more people will become involved in a job that allows them control and a chance to use their abilities than will become involved in jobs that are lacking these characteristics" (p. 311).

Patchen (1970) identified three general conditions for job involvement. According to him, "Where people are highly motivated, where they feel a sense of solidarity with the enterprise, and where they get a sense of pride for their work, we may speak of them as highly 'involved' in their job" (p. 7). When Patchen talks of workers being highly motivated, he refers to their high levels of achievement need or to their wish to accomplish worthwhile things on the job. When he talks of workers' solidarity with the enterprise, he refers to their need for belonging to the organization. Finally, when he talks of workers' sense of pride, he refers to workers' feeling of high self-esteem. Thus, in Patchen's view, when a job provides opportunities for the satisfaction of one's achievement needs, belonging needs, and self-esteem needs, one experiences a greater degree of job involvement.

In a recent review of the psychological literature on job involvement, Rabinowitz and Hall (1977, p. 284) stressed that among other things, a job-involved person believes strongly in the Protestant ethic, has strong growth needs, and has a stimulating job that gives him or her a high degree of autonomy and an opportunity for participation.

In another review of the psychological literature on job involvement, Saleh and Hosek (1976) identified four different interpretations of the concept of involvement: "A person is involved (1) when work to him is a central life interest; (2) when he actively participates in his job; (3) when he perceives performance as central to his self-esteem; (4) when he perceives performance as consistent with his self-concept" (p. 215). The first interpretation of the concept of involvement in terms of central life interest (Dubin, 1956) is very similar to the interpretation offered by Lawler and Hall (1970). The main idea underlying this interpretation is that the psychological state of involvement with respect to an environmental entity (such as job, family, etc.) is a cognitive or perceived state of identification with that entity. The second interpretation of involvement in terms of participation suggests that the psychological state of involvement be viewed as behavioral acts of the individual directed toward the satisfaction of his or her needs for autonomy and control. Bass (1965), for instance, considered participative job behaviors such as making important job decisions, setting one's own work pace, and so on to be important indices of greater work involvement. The remaining two interpretations of involvement, namely, providing a sense of personal worth (Siegel, 1969) and reinforcing one's self-concept (Vroom, 1964), suggest that involvement may be viewed as the experience of satisfaction resulting from the fulfillment of the individual's self-esteem and self-actualization needs. From the results of their own factor analytic work, Saleh and Hosek (1976) concluded that job involvement is "the degree to which the person identifies with the job, actively participates in it, and considers his performance important to his self-worth. It is, therefore, a complex concept based on cognition, action, and feeling" (p. 223). It is interesting to note that to achieve conceptual clarity Lawler and Hall tried to differentiate the state of involvement from intrinsic motivation and job satisfaction, whereas Saleh and Hosek brought them all together again.

At this point it must be noted that there is one common thread that runs through all the

psychological formulations outlined above. All of them seem to emphasize that situations lacking in opportunity for the satisfaction of intrinsic needs of the individual such as self-esteem, achievement, autonomy, control, self-expression, and self-actualization will decrease the individual's involvement in them. Even the recent studies on central life interest in work settings, on organizational identification, and on organizational commitment (Dubin, Champoux, & Porter, 1975; Hall & Schneider, 1972; Hall, Schneider, & Nygren, 1970) reflect this bias. It seems as if the lack of intrinsic-need satisfaction is the basic condition for increasing work alienation. In this regard, psychologists seem to have followed the sociological tradition of considering the lack of individual freedom, power, and control as necessary preconditions of the psychological state of alienation.

Sources of Confusion Surrounding the Concepts

Five major sources of confusion can be identified in the literature on alienation and involvement. Not only in the theoretical treatment of the concepts but also in the operationalization of the concepts in empirical studies, one notices the presence of these sources of confusion. They have contributed to the exasperating conceptual ambiguity prevailing in the area, and it goes without saying that any meaningful scientific treatment of the concepts should guard against them.

The most common source of confusion is the application of the concepts sometimes to specific individuals and sometimes to groups of individuals. Particularly in sociological writings one finds the use of the concept of alienation sometimes to describe the psychological state of the individual and at other times to describe pathological states of large collectivities such as groups, organizations, and other socio-political systems. As Johnson (1973) correctly pointed out, "There is a difference in meaning between these two applications that is not merely the difference between singular and plural categories. The phenomenology and the meaning connected with individual states of alienation are different both in quality and significance from those connected with the social, interactional, and collective applications of the term" (p. 35). For example, to say that a worker is alienated can mean two things. It can suggest an instance of *collective experience* of worker alienation as reflected in absenteeism, tardiness, goldbrick, sabotage, and so on that results from the prevailing social and physical conditions (mechanization, impersonal control through rules and regulations, etc.) within the organization, or it can suggest an individual worker's *personal view* of his or her work that does not meet his or her salient needs (unique to the individual) regardless of how other workers view the situation. From a methodological standpoint, it is advisable to approach the study of alienation at the personal rather than at the collective level of experience. Measurement and interpretation of the collective experience of alienation are often difficult and confusing.

A second source of confusion stems from the fact that the concept of alienation has been described and measured in two different ways. Sometimes the term alienation is used to imply objective social conditions directly observed by others and later attributed to individuals and groups. Blauner (1964), for instance, considered mechanization and division of labor to be the alienating conditions, and people working under these conditions were assumed to be experiencing alienation. At other times, alienation has been interpreted as a subjective psychological state of the individual not detectable to outsiders but felt by the individual. Such a difference in the usage of the term has obvious implications for the operationalization of the concept. States of alienation measured through identification of objective conditions may not parallel the subjective measures of the concept. Mechanization and division of labor in an organization may be viewed by external observers as necessarily contributing to a state of alienation of the worker (powerlessness), but the worker may not perceive the situation in the same way. In fact, it is quite conceivable that for some workers (mentally and physically handicapped, unskilled, uneducated, and many belonging to developing countries) mechanization and division of labor may increase job involvement.

A third source of confusion (related to the preceding one) results from a failure to maintain the conceptual distinction between the *antecedent conditions* of alienation and the *consequent states* of alienation. Here the confusion results from mistaking the cause as the effect. As Josephson and Josephson (1973) remarked, "Durkheim's notion of anomie or normlessness can be regarded as an important *cause* of alienation but should not be confused with alienation as a state of mind. . . . By the same token, alienation should not be confused with 'social disorganization,' since estrangement may be found in highly organized bureaucracies" (p. 166). In spite of such warnings, both the sociological and the psychological formulations neglect to maintain the distinction between alienating conditions and alienating states. In fact, most empirical researchers have attempted to measure the state of alienation through indices of alienating conditions instead of directly measuring it (as if the two were equivalent). For instance, Seeman (1959) considered normlessness to be the perception of a social situation in which rules and norms regulating behavior have broken down. Such perceptions may be the antecedent conditions of the alienated state, but they cannot be identified with the alienated state itself. Likewise, isolation, meaninglessness, and powerlessness may describe different conditions or causes of alienation, but should not be equated with it. Even when self-estrangement was measured by Blauner (1964), he used several indices of alienating conditions on the job, such as whether the job met the worker's achievement needs. Shepard (1971) also measured the different forms of alienation suggested by Seeman (1959) by measuring various job conditions such as whether the job provided opportunity for participation and control (powerlessness), how the job fit into the total operation of the organization (meaninglessness), and the like. Clearly these kinds of questions probe into the assumed conditions or causes of alienation rather than into the state of alienation itself. In the psychological literature similar confusion may be noted. For instance, Saleh and Hosek (1976) have proposed a measure of job involvement that contains three distinct categories of items. The first category measures directly the state of alienation (e.g., with the item "The most important things I do are involved with my job"). The second category seems to index the antecedent conditions or presumed causes of alienation (e.g., with the item "How much chance do you get to do things your own way?"). Finally, a third category measures workers' behaviors and experiences that often (but not necessarily) result from the alienated state (e.g., the item "I avoid taking on extra duties and responsibilities in my work"). Thus Saleh and Hosek combine indices of causal conditions and effects of alienating states into one single instrument. Such an instrument cannot provide meaningful data on the state of alienation of the worker. Needless to say, for both conceptual clarity and effective methodology in empirical studies, the state of alienation needs to be identified and measured separately from its causes as well as its effects.

A fourth source of confusion results from the description of the state of alienation as being both a *cognitive* as well as an *affective* state of the individual. Most researchers have found it difficult to strip the concept of alienation from its negative affect. Traditionally, alienation has been associated with negative emotional states such as anger, dissatisfaction, and unpleasantness, and involvement has been associated with positive emotional states such as satisfaction and pleasantness. Many measures of alienation or involvement therefore contain items reflecting levels of satisfaction or dissatisfaction (e.g., the item "The major satisfaction in my life comes from my job" in Lodahl & Kejner, 1965). Recent empirical studies (Lawler & Hall, 1970; Seeman, 1971) clearly suggest that work involvement and job satisfaction are not the same thing, although they may be related to one another. It may be more useful to conceptualize the states of involvement or alienation as cognitive or belief states of identity or dissociation (separateness) than as psychological states necessarily associated with feelings of satisfaction or dissatisfaction. A cognitive state of dissociation may or may not accompany positive or negative affect under certain conditions. A highly involved worker under some conditions may

feel a high level of satisfaction with his or her work and under other conditions may experience deep dissatisfaction. In the future, empirical work needs to be done to identify conditions under which involvement and alienation are related to positive, negative, and neutral affective states.

Finally, some ambiguity regarding the concept of alienation has resulted from the confusion of two kinds of causation, *contemporaneous* and *historical*. Sometimes the state of alienation in an individual has been viewed as the result of the past history of the individual. For instance, Lodahl and Kejner (1965) suggested that work involvement of an individual is determined by the early socialization process during which the individual internalizes the values of the goodness of work or the Protestant ethic. In this sense, alienation from or involvement with work becomes a more stable characteristic of the individual, which he or she carries with him or her from one situation to another. Sociologists have viewed the historical causation of alienation in a slightly different way. Following Marx, many sociologists have considered job experience to be central to an individual's life. According to them, the longstanding social arrangements of technology, division of labor, and capitalist property institutions have created the state of alienation from work (Blauner, 1964). Since work is central to one's life, alienation from work necessarily leads to alienation from all other aspects of life. As Seeman (1971) put it, "Perhaps the most important thesis concerns the centrality of work experience, the imputation being that alienation from work 'is the core of all alienation' and that the consequences of alienated labor color the life space of the individual in a profound and disturbing way" (p. 135). The state of alienation has also been conceived as being caused by contemporaneous events. For instance, Lawler and Hall (1970) consider the job-involved person to be one who is "affected very much by his whole job situation, presumably because he perceives his job as an important part of his self-concept and perhaps as a place to satisfy his important needs (e.g., his need for self-esteem)" (pp. 310–311). These authors therefore consider the worker's present perceptions of the need-satisfying potentialities of the job to be a major determinant of the state of involvement. From the above discussion, it is apparent that a state of alienation or involvement with regard to the specific aspects of one's environment (such as work, family, religion, etc.) may be jointly caused by two sets of events—one historical and the other contemporaneous. Through the socialization process (cumulative learning and experience of the past) the individual may develop a set of relatively stable beliefs and values regarding work, family, and so on, and the present experiences with them may either reinforce the beliefs and values or modify them.

A Motivational Framework for the Study of Alienation and Involvement

The following discussion is a description of a conceptual approach that can be used to study the phenomena of alienation and involvement in any specific aspect of one's life. To provide an example, however, I have chosen to discuss work involvement or the work setup as the specific environmental entity toward which a state of alienation or involvement may develop in an individual. The approach is characterized as a motivational one. It uses the existing motivational language to explain work alienation and involvement for two basic reasons. First, theories of human motivation at work (Maslow, 1954; Lawler, 1973) are generally advanced to explain all work behavior, and alienation and involvement at work should not be considered exceptions. Second, the fact that the existing motivational constructs can adequately and parsimoniously explain work alienation phenomena lies hidden in many of the sociological and psychological formulations discussed earlier. Thus, a clearer motivational formulation of the phenomena is needed to bring this fact to the surface. In addition to the use of motivational language, the present approach is characterized by an emphasis on the following considerations.

1. In defining the state of work alienation, the approach limits itself to the analysis of

the behavioral phenomenon at the individual level. It identifies the state of alienation with a cognitive belief state of the individual. As a cognitive state, work alienation becomes conceptually distinct from many associated covert feelings (affective states of the individual expressed in terms of satisfaction or dissatisfaction experienced on the job) and overt behavior (job participation, assuming responsibility, etc.).

2. The approach emphasizes that the state of work alienation must be clearly distinguished from its causes (antecedent conditions) and its effects (consequent conditions). It considers the phenomenon to be caused by two sets of events, historical and contemporaneous. The approach also stresses that the cognitive state of work alienation has significant effects on subsequent job behavior and job attitudes.

3. The present approach can integrate and adequately explain the different types of alienation at work suggested by sociologists within its own framework.

It may be argued that the concepts of alienation and involvement should not be reduced to a single dimension, since they represent two distinct types of behavioral phenomena. The phenomenon of alienation has been described by sociologists at the collective level (alienation of labor, alienated society, etc.), whereas the phenomenon of involvement has been identified by psychologists at the individual level (involved worker). A closer scrutiny of the issue, however, reveals that even when sociologists describe the concept of alienation at the collective level, they try to explain the phenomenon in terms of psychological states of the individual. A number of empirical sociological studies on alienation (Blauner, 1964; Seeman, 1971; Shepard, 1971) attest to this fact. If one considers the phenomena of both alienation and 'involvement' to be states of the individual, it would be more parsimonious to consider both concepts as representing a single dimension than to consider them as independent dimensions.

In the following description of the present approach, the above-mentioned characteristics are highlighted.

Definitions of the Concepts

In the present approach, work involvement is viewed as a generalized cognitive (or belief) state of psychological identification with work insofar as work is perceived to have the potentiality to satisfy one's salient needs and expectations. Likewise, work alienation can be viewed as a generalized cognitive (or belief) state of psychological separation from work insofar as work is perceived to lack the potentiality for satisfying one's salient needs and expectations. Thus, the degree of involvement at work should be directly measured in terms of individual's cognition about his or her identification with work. The individual's identification with this work, however, depends on two things: the saliency of his or her needs (both extrinsic and intrinsic) and the perceptions he or she has about the need-satisfying potentialities of work.

Defining the concepts in this way has some implications for their measurement. If job involvement and alienation are viewed as cognitive states of an individual, they cannot be measured with the existing instruments (Blauner, 1964; Lodahl & Kejner, 1965; Saleh & Hosek, 1976; Shepard, 1971). Most of these instruments combine some measures of the cognitive state of alienation with some measures of its presumed causes and effects. For example, the most widely used instrument, developed by Lodahl and Kejner (1965), contains not only items that reflect the cognitive state of involvement ("I live, eat, and breathe my job") but also items that reflect both antecedent and consequent feeling states and behavioral tendencies ("I feel depressed when I fail at something connected with my job" or "I will stay overtime to finish a job, even if I am not paid for it"). Because of such built-in ambiguities in the existing instruments, the data these instruments yield are often hard to interpret. Future research efforts should attempt to develop more unambiguous measures of job involvement that reflect only the nature of the cognitive state of psychological identification with work. For instance, items such as "I live, eat, and breathe my job," "I am very much involved in my job," "The most im-

portant thing that happened to me involved my work," and so on tend to reflect the individual's awareness of work identification without measuring his or her need states (antecedent conditions) or overt behavioral tendencies (consequent conditions). These kinds of items have construct validity and therefore are more desirable measures of the cognitive state of job involvement. One can also use graphic techniques or the semantic differential format (Osgood, Suci, & Tannenbaum, 1957) to measure job involvement on dimensions such as involved–noninvolved, important–unimportant, identified–separated, central–peripheral, and so forth. Besides being less confusing with regard to assessing the cognitive states of involvement and alienation, such measures of job involvement that have construct validity seem to be better suited for cross-cultural and comparative research than are the existing measures, because the latter tend to mainly include and heavily emphasize items on intrinsic-need satisfaction. For groups of people who do not consider intrinsic needs (autonomy, control, etc.) to be the guiding forces in their lives, the existing measures with an emphasis on intrinsic needs cannot truly reflect their job involvement.

Conditions of Job Involvement

A schematic representation of the present motivational approach to job involvement, its causes, and its effects is presented in Figure 1. As can be seen in Figure 1, an individual's behavior and attitudes exhibited both on and off the job are a function of the saliency of need states within him or her. At any given moment, the need saliency within the individual depends on the prior socialization process (historical causation) and on the perceived potential of the environment (job, family, etc.) to satisfy the needs (contemporary causation). The cognitive state of involvement as a by-product of need saliency also depends on the nature of need saliency as historically determined through the socialization process and on the perceived potential of the environment to satisfy the needs. In the context of job involvement, an individual's belief that he or she is work involved or job alienated depends on whether the work is perceived to have the potential for satisfying his or her salient needs. The saliency or the importance of different needs for the individual is determined by the individual's past experiences with groups of which he or she was a member (socialization process) and with jobs that he or she has held. Different groups of people are influenced by different cultural, group, and organizational norms, and thus they tend to develop different need structures or to set different goals and objectives for their lives. For example, the work-motivation literature suggests that the sources of work involvement for managers within any organization may be very different from those for the unskilled laborers because of differences in the need saliencies of the two groups. Managers may value more autonomy and control in their jobs, whereas the unskilled laborers may attach greater importance to security and to sense of belonging in their jobs. Such value differences stem essentially from past socialization processes and from the influence of the norms of the groups to which the workers belong.

In a recent study, Kanungo, Gorn, and Dauderis (1976) demonstrated that because of differences in the socialization process, francophone and anglophone managers exhibit different patterns of need saliency at work. For instance, security and affiliation needs seem to have greater saliency for francophone as compared to anglophone managers, whereas autonomy and achievement needs tend to have greater saliency for anglophone as compared to francophone managers. The salient needs tend to determine the central life interests of the individuals. On the job, the saliency of a need in an individual may be reinforced when the person finds that through job behavior he or she is capable of meeting the needs. His or her perception that the job is capable of satisfying his or her important needs will make the individual devote most of his or her available energy to the job. The worker will immerse himself or herself in the job, and the feedback from his or her job behavior will lead the worker to believe that the job is an essential part of himself or herself or that he or she is job involved. If, how-

ever, the job is perceived by the individual as lacking in opportunities for the satisfaction of his or her salient needs, he or she will develop a tendency to withdraw effort from the job and thus become alienated from it. For the satisfaction of his or her salient needs, the person will redirect his or her energy elsewhere by engaging in various off-the-job activities or by engaging in various undesirable on-the-job activities.

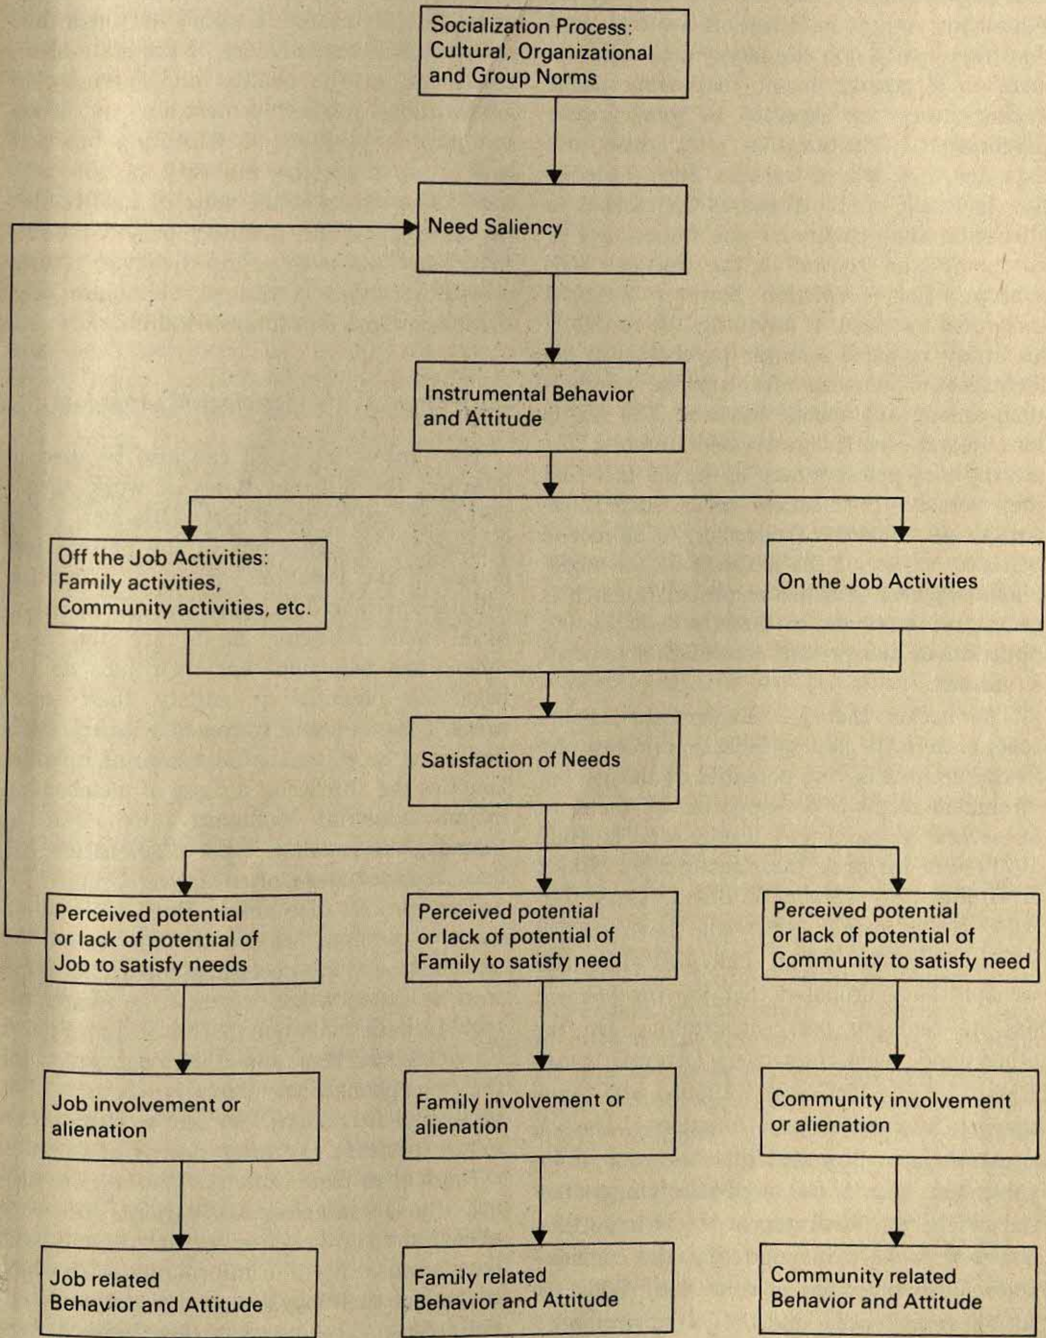

Figure 1. Schematic representation of the motivational approach to involvement and alienation.

A recent comparative study (Basu, 1976) of job involvement among francophone and anglophone workers has provided some indirect evidence in support of this motivational approach to work involvement. On the basis that anglophone workers are a product of the Protestant ethic socialization process and that they value job autonomy and achievement to a greater extent than francophone workers, they are expected to show greater psychological identification with their jobs than are francophone workers. Such a prediction is based on the previous approaches to alienation that emphasize the importance of autonomy and control in the worker's self-concept. This prediction however was not confirmed by Basu. If anything, the results of his study revealed stronger psychological job identification among francophone workers than among anglophone workers. The reason for greater work involvement among the francophone workers may lie in the fact that they perceive their salient needs, such as security and affiliation tendencies, to be met to a greater extent on the job than do the anglophone workers. Further empirical research is necessary, however, to directly test the implication of the present formulation in work situations.

The notion that job involvement has its roots both in the past socialization process and in the need-satisfying potential of the job environment seems to be supported by the work of several researchers (Rabinowitz & Hall, 1977). For instance, those researchers (Blood & Hulin, 1967; Hulin & Blood, 1968; Lodahl, 1964; Siegel, 1969) who have studied job involvement as an individual-difference variable have proposed that job involvement has its roots in past socialization. On the other hand, those researchers (Argyris, 1964; Bass, 1965; McGregor, 1960) who have studied involvement as a function of the job situation have proposed that the root of involvement lies in the need-satisfying potential of the job environment. It is important, however, to keep in mind that the cognitive state of involvement is caused by both the socialization process and the job environment. Future studies should be directed toward assessing the relative contributions of each of these causes of job involvement.

Figure 1 also suggests that a cognitive state of job involvement will have significant influence on job behavior and job attitudes. Several interesting possibilities present themselves in this regard. It would be worthwhile to investigate the influence of the state of involvement on the quality and intensity of job attitudes. Job involvement does not necessarily cause positive job attitudes, but perhaps does affect the intensity of job attitudes. The effects of the state of involvement on the quality and quantity of job productivity and on membership behavior (turnover, absenteeism, tardiness, etc.) also need to be investigated in future research.

Integration of the Sociological Approach

The present approach can also be used to interpret the different types of work alienation suggested by sociologists (Blauner, 1964; Seeman, 1959). In terms of the present formulation, the isolation variant of alienation will be experienced by those individuals whose social and belonging needs are the most salient and who find that their jobs do not have the potential to satisfy their social needs. Blauner seems to concur with this position when he states that the state of isolation "implies the absence of a sense of membership in an industrial community" (p. 24). In Canada, the isolation type of alienation has been reported more often among French Canadian workers than among English Canadian workers, perhaps because in the case of the former group, the necessary conditions for a state of isolation are present to a greater extent (salient affiliation needs of the French Canadian workers and their perception of the anglophone ownership of industry). For very similar reasons, female workers often may experience a greater degree of isolation at work than male workers. The normlessness and the meaninglessness variants of work alienation can be observed in persons who have a salient need for information with which to predict their physical and social work environments. Finding that their jobs do not provide the necessary information, they may

develop beliefs about the meaninglessness of their jobs. Educated and skilled workers may have a stronger need for information than lesss educated and unskilled workers. Hence the former group of workers may have a stronger tendency to develop beliefs about the meaninglessness of work than the latter group. Perhaps for similar reasons, the alienation of intellectuals tends to be of the meaninglessness variety (Seeman, 1959; Mills, 1951). The powerlessness type of alienated state may be experienced by individuals who have salient ego needs such as the need for autonomy, the need for control, and the need for self-esteem but who find the job environment incapable of satisfying them. Finally, the self-estrangement variety of alienation may be experienced by people who have highly salient self-actualization needs, such as the need for achievement, and find their jobs limiting the realization of their potentialities. Thus, from a motivational standpoint, the different types of alienation suggested by sociologists represent the same cognitive state of separation from an environmental entity and are different only in the sense that they are caused by the different saliency structure of needs in the individuals.

Some Major Differences Between the Present and the Earlier Approaches

At this point, it may be useful to compare and to highlight a few important differences between the present conceptualization and earlier ones.

Although the definitions of involvement and alienation as cognitive states of identification with work resemble the way the concepts were defined by Lawler and Hall (1970), the former are different from the latter in one important respect. As discussed earlier, Lawler and Hall (1970) put exclusive emphasis on the job opportunities that meet a worker's need for control and autonomy as necessary preconditions to the state of job involvement. In fact, all earlier formulations (both sociological and psychological) seem to have followed this line of thinking. The present approach, however, suggests that job involvement does not necessarily depend on job characteristics that allow for control- and autonomy-need satisfaction. It emphasizes that workers have a variety of needs, some more salient than others. The saliency of the needs in any given individual is determined by his or her past socialization in a given culture (historical causes) and is constantly modified by present job conditions (contemporary causes). Different groups of individuals, because of their different socialization training or different cultural background, may develop different need saliency patterns. They may value extrinsic and intrinsic job outcomes (Lawler, 1973) very differently. One set of needs (e.g., growth needs such as self-esteem and autonomy) may be salient in one group of workers, but the same needs may not be salient in another group. This may result in different self-images in the two groups and, consequently, in different job expectations in the two groups. One group of workers that considers control and autonomy to be the core of their self-image may get involved in jobs that are perceived as offering opportunity for exercising control and autonomy, and they may become alienated from jobs that are perceived as providing little freedom and control. Such job characteristics, however, may not be the crucial considerations for another group (who may view security and social needs to be the core of their self-image) in the determination of their job involvement or alienation. That people do differ with respect to what constitutes the core of their self-concepts should not be overlooked. The developed societies of the West may make their citizens believe that all that counts in one's life is to have individual liberty and freedom. Workers belonging to these societies may feel therefore that working life is of little worth without freedom and control. In contrast, however, in the developing societies of the East, economic and social security often are considered more important to life than are freedom and control. Thus, workers in eastern societies may find work very involving if it guarantees such security, but may not care very much for freedom and control in their jobs. In these societies, people may value equality more than liberty as the guiding principle of working life. Rabinowitz

and Hall (1977) alluded to this possibility, but found no available research that examined "this lower-need-based form of job involvement" (p. 280).

In their attempts to increase job involvement among workers, the sociological (Blauner, 1964) and the psychological (Lawler & Hall, 1970) approaches have analyzed the work situation from the standpoint of *job design*, or the nature of the job. They have emphasized job characteristics such as the lack of variety in a job, mechanized and routine operations, strict supervision, and so on and their effects on the involvement of workers without any attempt to understand the nature and the saliency of needs in the workers. In presenting such a position, these authors have argued in favor of a universal prescription for increasing job involvement by designing jobs to provide greater autonomy and control to the workers. The prescription is of course based on the assumption that the needs for control and autonomy are the most salient needs in workers. This position can be contrasted with the approach that Taylor (1911) advocated in his principles of scientific management. In his pig-iron-loading experiment, he selected as his subject a physically strong individual who had salient monetary need. In selecting the right man for the job, he looked into the past training and abilities, the need saliency, and the job perceptions of the worker. Obviously, Taylor must have thought that these characteristics have a significant influence on a worker's job involvement. The approach advocated in this article does not make the assumption that the needs for control and autonomy are the most salient needs in all workers. Unlike previous approaches, the present approach suggests that job involvement can be best understood if we find out the nature of and the saliency of needs in workers as they are determined by prior socialization and present job conditions. The design of jobs and the determination of their extrinsic and intrinsic outcomes for the sake of increasing job involvement should be based on an understanding of worker needs and perceptions. The findings of Lawler and Hackman (1971) seem to support this position. According to them, "There is no reason to expect job changes to affect the motivation and satisfaction of employees who do not value the rewards that their jobs have to offer" (p. 52).

Previous approaches emphasized the distinction between work as instrumental and work as consummatory activity (the means to an end vs. the end in itself). The present approach considers work to be a set of job-related behaviors and attitudes and, like all behaviors and attitudes, work is considered to be instrumental in satisfying a variety of needs that a worker may have. All human behaviors stem from need states, and all human behaviors tend to be purposive and instrumental in obtaining goals or outcomes for the satisfaction of needs. Work behaviors and job attitudes should not be an exception to this rule.

In summary, the motivational approach to the study of alienation and involvement advocated in this article provides an integrative framework for future psychological and sociological research. Future research in the area should not only attempt to measure job alienation and job involvement as cognitive states but also attempt to relate such cognitive states to the antecedent conditions of need saliency in the individual and his or her job perceptions. Attempts should also be made to relate the cognitive states of alienation and involvement to the various affective states that accompany them and to their behavioral consequences. Using the motivational approach, future studies should explore the phenomena of alienation and involvement in areas other than work, such as in the family, in the community, and in other forms of leisure-time pursuits (as suggested in Figure 1). It would be of considerable interest to find out the reasons for alienation and involvement in these areas for different groups of people with different socialization training. It would also be of interest to see how involvement and alienation in one area influence the nature of such states in other areas. For instance, how does job involvement affect family involvement and vice versa? The widely accepted Marxian dictum that work alienation is the cause of all social maladies is something that clearly

needs empirical verification. These are some of the general issues that need exploration in the future, and it is hoped that the framework proposed here will help in such exploration.

Between-Subjects Expectancy Theory Research: A Statistical Review of Studies Predicting Effort and Performance

Donald P. Schwab, Judy D. Olian-Gottlieb, and Herbert G. Heneman III
Graduate School of Business and Industrial Relations Research Institute
University of Wisconsin—Madison

A large number of between-subjects expectancy theory studies have correlated measures of employee motivation (force) to perform (consisting of perceptions regarding linkages among effort and performance, performance and outcomes, and the attractiveness of the outcomes) with measures of effort and performance. The results of these studies (i.e., variance explained in effort and performance) vary considerably. A statistical review of these studies was conducted to determine the extent to which variance explained (the dependent variable) was a function of various characteristics of the effort and performance and of the force-to-perform measures (the independent variables). There were 160 observations, derived from 32 studies. Using multiple regression, we found that variance explained in these studies was greater when (a) self-report or quantitative measures of effort and performance were used rather than evaluations of these variables by someone other than the subject; (b) 10–15 outcomes were included in the force measure rather than a greater or smaller number of outcomes; (c) outcome valence was numerically scaled with positive numbers only, and the scale values were described in terms of desirability rather than importance; and (d) the force measure either contained no assessment of expectancy or an assessment that confounded expectancy and instrumentality. These variables accounted for 42% of the variance in the results obtained in the studies reviewed. Some theoretical and research implications of these findings are discussed.

Expectancy theory (Vroom, 1964) is a process theory of work motivation that has received considerable theoretical and empirical attention. Although numerous variations of the theory have been proposed (Campbell & Pritchard, 1976), the core of all formulations is the proposition that motivation (force) to perform is a function of (a) the expectancy that changes in effort will result in changes in performance, (b) the instrumentality of performance changes for the attainment of outcomes (such as pay increases), and (c) the valences of the outcomes. Also, in most formulations, these variables are combined in a multiplicative fashion as follows: Force to perform = f[expectancy $\times$ Σ(instrumentalities $\times$ valences)].

A substantial amount of research has been stimulated by expectancy theory. Almost all of it has used a between-subjects design in which a measure of force to perform is correlated with a measure of effort or performance for a sample of individuals. Some reviewers have objected to this orientation and have suggested that a within-subject design would be more appropriate for testing the theory (e.g., Mitchell, 1974). To date, how-

A preliminary version of this article was presented at the meeting of the National Academy of Management, Orlando, Florida, August 1977. The authors gratefully acknowledge the comments and criticisms of Chris Berger, Gil Churchill, and Larry Cummings in earlier stages of the project.

Requests for reprints or for a list of the studies reviewed in this article should be sent to Donald P. Schwab, Graduate School of Business, University of Wisconsin, 1155 Observatory Drive, Madison, Wisconsin 53706.

ever, there has been almost no such research on the prediction of effort or performance.

As the body of empirical literature on this theory has proliferated, so also have reviews summarizing and interpreting that literature (e.g., Campbell & Pritchard, 1976; Connolly, 1976; Heneman & Schwab, 1972; House, Shapiro, & Wahba, 1974; Mitchell, 1974; Mitchell & Biglan, 1971; Wahba & House, 1974). Although some of these reviews are essentially uncritical descriptions of the theory and research findings (e.g., House et al., 1974), all have made at least some suggestions aimed at improving the conduct of future research.

The suggestions that have been made can be viewed from two related perspectives. One is primarily theoretical in orientation. From this perspective, reviewers can be viewed as encouraging their empirically oriented colleagues to test expectancy theory qua theory. Thus, as examples, Heneman and Schwab's (1972) admonition to include assessments of expectancy in force measures and Mitchell's (1974) plea to perform within-subject studies can be viewed as attempts to make the measures and procedures of empirical investigations isomorphic with the theory.

An alternative perspective is to view these suggestions as aimed at increasing the theory's ability to predict effort or performance. The focal point of such an orientation is in increasing variance explained rather than in the elegance of the theoretical formulation per se. The reviews mentioned here have generally made suggestions regarding the measurement of the constructs specified in the theory. These recommendations, however, have in every case been based on casual assessments of previous research; that is, none of the reviews have empirically determined if variance explained differs as a function of the measurement procedures used.

The present review involves a statistical analysis of the results obtained in previously published between-subjects studies of expectancy theory. Studies included in our statistical analysis were those that examined the amount of variance explained in measures of effort or performance by measures of force to perform. These variance-explained values reported in the previous studies became our dependent variable. Independent variables chosen for the statistical analysis were various characteristics of (a) the measures of performance or effort and (b) the force measures that were used in the previously published research. Thus, the present study aims to account for variation in the strength of the relationship observed in other studies between force to perform and performance or effort as a function of characteristics of the effort, performance, and force-to-perform measures.

Three issues were examined regarding characteristics of the performance and effort measures. The first of these involved distinguishing between use of effort and use of performance as criterion measures. The conception of force is clearly aimed at predicting the effort expended toward some behavior. The actual behavior (job performance in the case at hand) is seen as a multiplicative function of force to perform and ability to perform (Vroom, 1964). Thus, from a theoretical perspective, one might argue, *ceteris paribus*, that more variance would be explained in studies using effort as the dependent measure than in studies using some measure of performance.

There is, however, reason to suspect that measures of effort might not be more predictable than measures of performance. Specifically, as Campbell and Pritchard (1976) have stated, "Organizational psychology is without any clear specification of the meaning of effort and consequently there is no operationalization of the variable that possesses even a modicum of construct validity" (p. 92). Thus, one might anticipate difficulty in predicting effort from force on pure measurement grounds.

A second dependent variable issue pertained to whether the measure was internal (self-reports) or external (others' ratings and rankings or productivity indexes) to the subject. Mitchell (1974) has argued that internal measures are more appropriate because effort is difficult to observe and hence measure externally. Moreover, it is generally agreed that when self-ratings are used simultaneously

for both the dependent and the independent variables, the resultant correlations are inflated. Thus, we hypothesized that more variance would be explained when self-ratings were used to measure effort or performance than when alternative measures were employed.

A third issue regarding the dependent variable was concerned with performance measures that were external to the subject. These measures have typically been ratings or rankings of performance provided most often by the subject's work supervisor. There have also been a number of instances in which investigators had access to quantitative productivity measures (units produced, sales volume, etc.). We hypothesized that more variance would be explained with the latter measures because of the reliability problems that frequently occur with performance ratings or rankings.

It was also possible to examine a number of issues dealing with characteristics of the force measure used. One important issue had to do with the number of outcomes (i.e., consequences of performance) assessed. Both Heneman and Schwab (1972) and Mitchell (1974) have suggested that a theoretical orientation would require that a large number of such outcomes be included in any test of the theory. This would be necessary to ensure that all outcomes of potential relevance to subjects are included in the measure of force to perform. No harm would come from this strategy because outcomes of no importance (with zero valence) would fall out of the force equation. For example, an outcome such as *improved recreational facilities* might not be important to most subjects. They would be expected to assign such an outcome zero valence, and hence it would not enter their force-to-perform equations. Nevertheless, including such an outcome would presumably enhance the force-to-perform estimates of those subjects for whom this outcome has some nonzero valence.

Again, however, psychometric issues potentially conflict with theoretical precision. Outcomes of little importance to subjects may contribute to unreliability of measurement and hence to reduced predictability. The potential conflict between theoretical and psychometric considerations suggests that a nonlinear relationship between number of outcomes and variance explained might be hypothesized. Up to a certain point increases in the number of second-level outcomes may increase variance explained because the marginal increment in total valence is large relative to the reliability decrement. We hypothesized, however, that beyond some point the marginal increment would be offset by the reliability decrement, resulting in a reduction in the variance explained.

The data permitted the examination of two issues involving the measurement of valence of second-level outcomes. One of these issues has to do with the verbal anchoring of the valence measures. Vroom (1964) defined valence as indicating anticipated satisfaction with, or desirability of, second-level outcomes. Both Connolly (1976) and Mitchell (1974) noted that many studies have anchored their valence scales with *importance,* which potentially represents an alternative construct. Connolly (1976) argued that unless the use of importance can be justified in variance-explained results, "There is a good argument for returning to the original conception of valence as anticipated satisfaction, or a close analog such as attractiveness, desirability, or anticipated utility" (p. 40). The second issue regarding valence has to do with the numerical anchors used. Again Mitchell (1974) has argued that theoretical purity requires that the anchors range from positive to negative values instead of using just the positive values that are frequently reported. Both of these valence issues (importance vs. desirability and positive to negative vs. positive only) were examined in the present study, although directional hypotheses were not specified a priori.

The final issues considered in the present study pertain to the measurement of expectancy. In their review Heneman and Schwab (1972) pointed out that most of the initial studies failed to measure expectancy at all or confounded expectancy with measures of instrumentality. They urged that future research include unconfounded mea-

sures of expectancy. This plea has apparently been heeded because a number of investigations have now been reported that include expectancy measures unconfounded with instrumentality. Moreover, Campbell and Pritchard (1976) concluded that measures of expectancy, considered singularly, tend to be positively correlated with measures of effort and performance. Thus, it was hypothesized that variance-explained values would be greater when the force measure included an expectancy term than when it did not. It was also hypothesized that more variance would be explained when this measure was not confounded with instrumentality. A related issue was the measurement of expectancy in those studies that included an unconfounded measure. Vroom (1964) defined expectancy as the subjective probability that an outcome (e.g., performance) will follow a specified level of effort. Thus, a theoretically correct measure of expectancy would assess it in likelihood terms, although in a number of studies it has been measured in alternative ways (e.g., having subjects compare the importance of personal effort relative to other potential determinants of performance; Schwab & Dyer, 1973). Following this theory we hypothesized that more variance would be explained when expectancy was measured in subjective-probability or likelihood terms.

Method

Dependent Variable and Population

The dependent variable was the amount of variance explained in a measure of effort or performance by a measure of force.[1] These values were easily obtained in studies that reported results in correlational terms by computing coefficients of determination (r^2 or R^2). The R^2 values were corrected for number of independent variables using Nunnally's (1967) correction formula. In two studies the results were not directly presented in correlational terms, but it was possible to derive the correlation from the information presented (Lawler, 1966; Turney, 1974).

A number of decisions about choice of the dependent variable were made. Many studies reported a variety of analyses; for example, performance might be correlated with a number of alternative force formulations. In these instances, data were used only from the model that most closely approximated the multiplicative force model specified earlier.[2] In addition, we included only the force measure that used the total number of outcomes assessed in the study. In the four studies that used cross-lagged correlation analysis (Kopelman & Thompson, 1976; Lawler, 1966; Lawler & Suttle, 1973; Sheridan, Slocum, & Richards, 1974), only the predictive results (force at time 1, effort or performance at time 2) were used. In all instances only one model of force was included from each study. However, an observation corresponding to each relationship between the force measure and alternative measures of effort or performance was included from those studies that had multiple measures of effort or performance.

A total of 32 published studies (using effort or performance measures as criteria) were found in which the results were reported in such a manner that a variance-explained value was presented or could be derived. Using the decision rules specified previously, a total of 160 observations were extracted from the 32 studies. For analysis purposes we viewed this $N = 160$ as the population of variance-explained values in between-subjects studies.

Independent Variables

The studies were reviewed to obtain the necessary independent variable information. Since the information was relatively straightforward, little ambiguity occurred in reviewing the studies and coding the data. The following independent variables were used in the present study: (a) whether effort or performance was measured, (b) whether the effort/performance measure was self-reported or externally assessed, (c) whether the externally assessed measure was based on objective data (e.g., sales volume and productivity) or subjective appraisal, (d) number of second-level outcomes (trichotomized into categories of approximately equal numbers of observations consisting of 1–9 outcomes, 10–15 outcomes and 16 or more outcomes), (e) whether valence was scaled positive to negative or only positive, (f) whether the verbal anchor for valence was importance or desirability,[3] (g) whether an expectancy

---

[1] The dependent variable used in the present study resulted in the exclusion of certain well-known expectancy studies (e.g., Georgopolous, Mahoney, & Jones, 1957; Porter & Lawler, 1968) because their results could not be cast into a variance-explained format. Also, negative force–performance (or force–effort) relationships were coded zero in the analysis.

[2] One exception to the decision rule was made for the Oliver (1974) study. He did not report results for the multiplicative model alone. Thus, the variance-explained estimate recorded for his study consisted of the multiplicative and additive models combined.

[3] In coding the verbal valence anchors, Graen's (1969) essential–unnecessary categories were coded

measure was included in the force measure, (h) whether the expectancy measure was unconfounded with instrumentality, and (i) whether expectancy was measured as a likelihood estimate.

Analysis

All independent variables were dummy coded (Cohen, 1968). The frequency with which each category appeared in the studies reviewed is shown in Table 1. Table 1 shows, for example, that 28 of the observations had an externally assessed productivity measure, that 29 had a self-report measure of effort, and so forth. Frequencies within each general category (dependent variable, number of outcomes, valence characteristics, and expectancy characteristics) sum to the total ($N = 160$) because they are made up of mutually exclusive and exhaustive subcategories. The mean variance explained was calculated for each of the categories shown in Table 1. In addition, the variance-explained values were regressed on various combinations of the dummy categories. This analysis was performed to assess how much of the variability in the results of previous research could be accounted for by the procedural characteristics of the studies. All multiple coefficients of determination reported in subsequent tables are significant ($p < .05$). However, significance levels are not reported in the tables because we view this analysis as describing the population of between-subjects, variance-explained estimates of effort and performance. Some inferential implications of this study are considered in the discussion.

Results

The first analysis involved an examination of the variance-explained values from the 160 observations in terms of the characteristics of the variables used to measure effort and performance. Table 2 reports the average variance explained between measures of force and the five classifications of the dependent variables employed in the studies reviewed. As hypothesized, force and self-report measures of effort and performance are more highly related than are force and others' assessment of effort or performance. For example, measures of force account for 10% of the variance on the average in self-report measures of performance and for 7% in performance measures assessed by others. Table 2 also shows, as hypothesized, that quantitative measures of productivity are more predictable than others' ratings or rankings of performance or effort. On the other hand, effort was less predictable than performance only for others' ratings and rankings. Overall, method of categorizing the measures of effort and performance accounted for 8% of the variability in the variance-explained values.

as important–unimportant. Coded as desirable–undesirable were good–bad (Hackman & Porter, 1968; Lied & Pritchard, 1976; Matsui & Terai, 1975), attractive–unattractive (Pritchard & Sanders, 1973), and preferences among pairs of outcomes (Sheridan et al., 1974).

Table 3
Variance Explained as a Function of Number of Outcomes

Number of outcomes	M variance explained
≤ 9	.08
10–15	.14
≥16	.05
R^2	.12

Table 3 shows the variance that force measures account for in measures of performance and effort as a function of the number of outcomes assessed. As hypothesized, highest average variance is explained in studies with an intermediate number of outcomes (14%), somewhat less variance is explained in studies with 9 or less outcome (8%), and the least variance is explained in studies with 16 or more outcomes (5%). Twelve percent of the variability in the results of the studies reviewed is accounted for by this categorization of the number of outcomes.

Preliminary analysis found that the numerical (negative to positive vs. positive only) and verbal (desirability vs. importance) anchoring procedures for valence measures were not independent (see Table 1). As a consequence, four categories were established for valence, as shown in Table 4. It can be seen that desirability scalings on the average have yielded higher variance-explained estimates than have importance scalings. Thus, Vroom's (1964) original definition receives some empirical support in terms of the verbal anchors. On the other hand, Table 4 shows that positive-only anchors, especially when combined with desirability anchors, have resulted in the highest average variance explained. All told, the scaling of valence accounts for 10% of the variability in the results obtained in the expectancy research reviewed here.

Table 4
Variance Explained as a Function of Valence Characteristics

Characteristic	M variance explained
Importance	
Negative–positive	.05
Positive only	.08
Desirability	
Negative–positive	.07
Positive only	.16
R^2	.10

Table 5 shows average variance explained as a function of the measurement of expectancy. Contrary to the hypothesis, greatest average variance is explained in studies that did not include a measure of expectancy (12%) or that confounded this measure with instrumentality (14%). Moreover, slightly less variance is explained in studies that used a likelihod estimate (5%) than in those that used alternative procedures (6%) among studies that did include an unconfounded measure. Twelve percent of the variability in the results of the studies reviewed is accounted for by the categorization of the procedures used to assess expectancy.

A final equation was generated by regressing the variance explained in previous expectancy studies on all of the independent variables simultaneously. The signs of the regression coefficients in this equation were the same as in the equations generated to obtain R^2 values in Tables 2–5. The R^2 for this last equation was .42. Thus, 42% of the variability in the results of the studies reviewed is accounted for by the categorizations of the dependent variables and force measures.

Discussion

At the outset it is important to recognize that our analysis was necessarily constrained by the measures and procedures used in the studies reported in the literature. Thus, as an example, Heneman and Schwab (1972) called for comparisons of results obtained using additive versus multiplicative combinations of force measures. Schmidt's (1973) criticism of multiplicative analyses aside, the present study was forced to consider multiplicative models because of those studies included in this review, only the Dyer and Weyrauch (1975), Oliver (1974), Pritchard and Sanders (1973), and Schwab and Dyer (1973) studies reported additive (or additive plus

interactive) combinations of all force components in addition to the multiplicative mode of combination.

An additional issue that could have been investigated, but was not, is the distinction between models that contrast results obtained using so-called intrinsic versus extrinsic outcomes. House et al. (1974), Wahba and House (1974), and Mitchell (1974) have all urged that such distinctions be made, and, indeed, a number of studies have purportedly done so (e.g., Mitchell & Albright, 1972; Oliver, 1974). However, such distinctions seem arbitrary in view of Dyer and Parker's (1975) demonstration that one social scientist's extrinsic outcome is another's intrinsic outcome and vice versa. As a consequence, we considered only the models in each study that included all outcomes.

Nevertheless, the issues that were investigated in the present review accounted for a substantial portion of the variance in the results of between-subjects expectancy theory studies designed to predict effort or performance. This was accomplished by categorizing several characteristics regarding the operationalization of the dependent variable and of force to perform. We found that self-report measures were more highly related to measures of force than were measures provided by other evaluators. This finding has been observed by other reviewers and probably reflects spurious method covariation. Objective measures of performance were also associated with greater variance explained than were measures obtained from other evaluators. There are at least two possible explanations for the higher predictability of objective measures. One possibility is that quantitative measures are more reliable than measures provided through an appraisal process. An alternative explanation has to do with the possible boundary conditions of the theory. Dachler and Mobley (1973) have suggested that the theory may only be predictive in situations in which outcomes are objectively linked to behaviors. It may be that in situations in which performance is objectively measured, the organization is more likely to use contingent reward systems (particularly those involving monetary rewards).

The composition of the force measure used was also related to the results obtained by previous researchers. Studies that used 10–15 second-level outcomes obtained stronger relationships between force and performance or effort than did studies that used either fewer or more outcomes. Additionally, studies that scaled valence only positively and that used desirability–undesirability verbal anchors resulted in more variance explained than alternative formulations of valence. Studies that did not measure expectancy at all or that confounded expectancy with instrumentality measures obtained stronger results than those that measured expectancy in a more theoretically correct fashion.

It is obvious from these results that maximum variance explained in between-subjects predictions of performance or effort has not been obtained by making force measures adhere to the theory. Indeed, every finding regarding the measurement of force could be interpreted as contrary to the theory except for the verbal anchoring of valence. Models have yielded the strongest results without a theoretically appropriate expectancy measure, with a moderate number of second-level outcomes, and with valence scaled only in a positive direction.

It is tempting to infer from these findings the likely results that would be obtained if one were to conduct a between-subjects study of performance or effort based on expectancy theory. The major probable constraint on inference, however, stems from the fact that multiple observations were taken from many of the studies reviewed. This clustering of observations within studies results in the probable underestimation of the standard

error of estimates and hence in the overestimation of the corresponding *F* values (Kish, 1957). Unfortunately, since the nonindependence of dependent values within clusters, if any, is confounded with the impact of the independent variables investigated, we know of no way to identify the magnitude of the problem and still retain all 160 observations.

We attempted to obtain some information regarding the appropriateness of generalization by replicating the analyses performed on the population in two independent subsamples drawn from the population. These samples were obtained by randomly choosing one observation per study, subject to the constraint that an observation could appear only once in the two samples. This procedure resulted in subsamples of $n = 31$ and $n = 27$ (six studies had only one observation). Variance explained was used as a dependent variable, as were two transformations aimed at generating a dependent distribution approximating normality. The first was Fisher's r to z transformation, and the second was a transformation derived according to procedures suggested by Hinkley (1977).

Generally speaking, the direction of results from these analyses was similar to the direction of results obtained on the population of observations. Self-report dependent variables were more predictable than others' reports in both samples, as in the population. Productivity was more predictable than others' reports in one sample, but the two were about equally predictable in the other. The intermediate number of outcomes was associated with highest average variance explained in one sample. In both samples, as in the population, lowest variance explained on the average occurred in the category with 16 or more outcomes. Also as in the population, valence scaled only positively resulted in greater variance explained in both samples. Moreover, in both samples the average variance explained was greater in studies that did not measure expectancy or that confounded this measure with instrumentality.

However, none of the coefficients of determination generated on the variance-explained values or on the transformed values were statistically significant ($p < .05$) in either sample. This lack of significance is probably due to the small sample sizes that were necessary to achieve independence of observations, as well as due to the large numbers of independent variables (relative to sample size). Thus, inferences drawn about the probable outcomes of future research findings from the results obtained here must be made cautiously.

Despite these qualifications, there is a nagging suspicion that expectancy theory overintellectualizes the cognitive processes people go through when choosing alternative actions (at least insofar as choosing a level of performance or effort is concerned). The results of the present review are consistent with this suspicion. At the very least, whether for theoretical or measurement reasons, our results indicate that complicated measures of force have not aided prediction in between-subjects investigations.

The Solzhenitsyn Finger Test: A Significance Test for Spontaneous Recovery

Edmund B. Coleman
University of Texas at El Paso

Spontaneous recovery is generally considered to be an unreliable phenomenon, but this is because of the fact that an inappropriate significance test has been used in past research. The research hypothesis states that spontaneous recovery is a monotonic function of time. Time is an ordered continuous variable; it flows steadily in one direction. The interaction test that has been traditional, however, is only appropriate for an unordered discrete variable. To illustrate this point, the study most frequently cited as evidence against spontaneous recovery was retested with significance tests appropriate for an ordered variable (specifically, the correlation coefficients tau and rho), and the findings were shown to be evidence for, not against, a recovery effect.

Spontaneous recovery in verbal learning is not widely considered to be a reliable phenomenon. In his general text on verbal learning, Jung's (1968) first sentence about the topic is, "Evidence regarding spontaneous recovery has been weak" (p. 118). Saltz (1971) wrote, "None of the studies . . . has reported evidence supporting the spontaneous recovery theory of proactive inhibition" (p. 218). Much the same evaluation is found in other texts and in reviews (Hall, 1971, p. 492; Hulse, Deese, & Egeth, 1975, p. 353; Keppel, 1968, p. 185).

But after an overall review of the research, Brown (1976) reached a different conclusion and suggested that the problem may be "that a more sensitive statistical or analytical measure may be required" (p. 336). The purpose of this article is to state Brown's suggestion in stronger language. The spontaneous recovery design needs a *correct* analysis; the interaction test that has been used for over 20 years does not fit the research hypothesis.

The most frequently cited study of spontaneous recovery (Koppenaal, 1963) can serve to illustrate the design and traditional analysis. Koppenaal used an A-B, A-C paradigm; that is, his subjects first learned an A-B list (*shiny–bitter*) and then an A-C list (*shiny–pretty*). There was also a control group who learned a single list. Figure 1 presents his findings, but the plot has been simplified by omitting data unrelated to the present argument. The traditional test for spontaneous recovery has been to test the mean square of the interaction between lists and time. Koppenaal's nonsignificant F of 1.30 and similar findings by Slamecka (1966) have been widely cited as evidence against spontaneous recovery. But given Brown's (1976) analysis of the overall evidence, the negative evaluation of spontaneous recovery findings by those in the field becomes unconvincing. A reexamination of the statistical logic appears in order.

The Solzhenitsyn Finger Test

In *August 1914* (1971/1972) Solzhenitsyn has his alter ego demonstrate to General Samsonov that the Russian front line is dangerously overextended with what could be called the Solzhenitsyn Finger Test, an important advance in instrumentation over the Interocular Traumatic Test (Edwards, Lindman, & Savage, 1963). Colonel Voro-

Requests for reprints should be sent to Edmund B. Coleman, Department of Psychology, University of Texas, El Paso, Texas 79968.

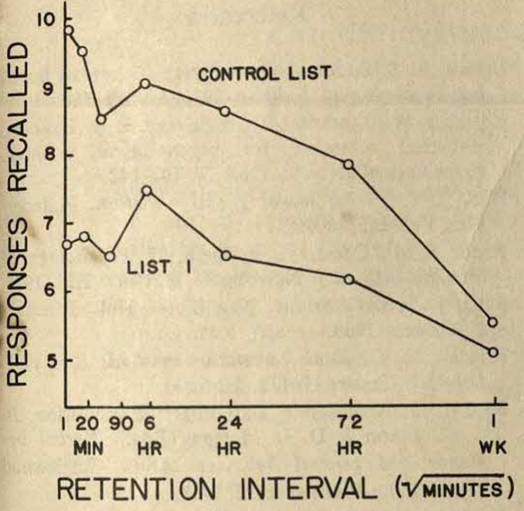

Figure 1. Number of correct responses for List 1 and the control list. The data are from Koppenaal (1963).

tyntsev, using his fingers as dividers, swings off six spans on the war map, showing Samsonov that his front-line troops are 6 full marching days ahead of staff headquarters.

Let us apply Colonel Vorotyntsev's finger test to the curves of Figure 1. The research hypothesis is that as time passes, the suppressed associations in List 1 spontaneously recover, thus causing its curve to converge toward the curve of the control list. Using your fingers as dividers, measure the difference between List 1 and the control list for the 1-minute interval. It will be about 3.2 responses. Now do the same for the 20-minute interval. It will be smaller—about 2.8 responses. If you continue for the longer and longer intervals, you will get smaller and smaller differences.

The charade has been pushed dangerously close to the point of insult. The point is that time is an ordered continuous variable; it only flows in one direction. Thus, the research hypothesis predicts an *ordered* decrease in differences; the significance test that has been in use for over 20 years, however, is *unordered*. Researchers have been using the interaction between lists and time, and that interaction is based on the unordered variance between the differences. The interaction mean square for Koppenaal's curves would have been exactly the same if the largest difference (3.2) had occurred at the second interval, the third interval, or at any other interval including the one for 1 week.

There are a number of powerful tests that fit an ordered hypothesis like the one for spontaneous recovery—the difference between correlation coefficients, the difference between slope coefficients, the linear component of the differences between the curves, and the like. Applying the more powerful tests to Koppenaal's data, however, would require estimation of certain terms and extensive justification of these estimations. A more economically presented test could be based on Kendall's (1962) tau. Since the test would use the degrees of freedom for the seven intervals instead of those for Koppenaal's 168 subjects, it would be somewhat overconservative; but perhaps that is a virtue in the present context.

For the seven intervals, the differences between the two curves are 3.2, 2.7, 2.15, 1.55, 2.2, 1.6, and .5. The research hypothesis (that as List 1 spontaneously recovers over time, the differences will become progressively smaller) can be expressed as 18 predictions: The difference between the curves at the 1-minute interval will be larger than the following six differences (all 6 predictions are correct). The difference at the 20-minute interval will be larger than the following five differences (all 5 predictions are correct). The difference at the 90-minute interval will be larger than the following four (3 predictions are correct and 1 is incorrect), and so on, as per Kendall (1962). Out of the 18 predictions, 15 conform to the research hypothesis. The ratio of 15 to 3 can be evaluated by Kendall's table of S values ($S = 18 - 3 = 15$) and is significant ($p < .015$, one-tailed).

An approach with the same underlying logic is to correlate the seven differences with their intervals ($\rho = .82$, $p < .025$). If one uses a more powerful test that replaces the degrees of freedom for the seven intervals with the degrees of freedom for Koppenaal's (1963) 168 subjects, the significance level will become more extreme. In short, the

finding most frequently cited as evidence against spontaneous recovery is, on the contrary, strong evidence in its favor.

In his Table 1, Brown (1976) listed 21 studies of spontaneous recovery. All 21 showed a trend toward recovery, but 8 of them (including Koppenaal's) reported a nonsignificant interaction. If the studies were retested with an ordered test, it is likely that several more of the negative reports would turn out to be evidence in favor of spontaneous recovery.

It is important to note that Type I errors are possible when the interaction is used to test an ordered function. In the case of spontaneous recovery, it is true, the opposite error is more likely to have been made. Because of the excessive weakness of the inappropriate test, which in turn led to a few incorrect negative evaluations, several characteristics of spontaneous recovery that are cornerstones of its theoretical relevance have not been vigorously pursued as research topics, for example, recovery over long intervals, recovery of specific suppressions, recovery of bonds not taught in laboratory lists, and others. Given the warranted power of an ordered test, perhaps such characteristics will appear in future research.

On the Nature of Taste Qualities

Donald H. McBurney and Janneane F. Gent
University of Pittsburgh

The concept of four basic tastes developed historically on the basis of a number of criteria. Modern evidence, largely electrophysiological, has led some investigators to reject the concept of basic tastes in favor of a taste continuum or multidimensional space. The present article reviews data that support the validity of the basic tastes. It is concluded that this concept, as well as the separate question of taste as an analytic or synthetic sense, is compatible with either of the two major positions on sensory coding in taste, labelled line theory and pattern theory. Taste may profitably be considered to comprise four distinct but interacting sensory modalities or submodalities analogous to the (other) skin senses.

Every introductory psychology text informs its readers that there are four taste qualities: sweet, salty, sour, and bitter. Such a statement may reflect the views of a majority of workers in taste at the present time, but it glosses over a long historical development and considerable current ferment (McBurney, 1974). On the one hand, those in the psychophysical tradition tend to accept the consensus of four taste qualities because of its obvious convenience and predictive usefulness. Those who are more physiologically oriented, however, tend to reject the notion of four taste qualities as naive. For example, Uttal (1973) wrote, "The psychophysical evidence continually seems to evoke the use of the four basic taste words. Yet . . . it is moot whether this must be interpreted as a reflection of the underlying biological mechanisms or of the evolved language of gustatory experience" (p. 603). Similarly, Schiffman and Erickson (1971) commented with respect to their psychophysical model of taste, "We would like to emphasize that the present model does not require, or support, the idea of taste primaries. That is, although the ordering of stimuli may, with some imagination, be seen as resulting in four rather indistinct stimulus groups . . . we do not suggest here that . . . any of these stimuli may be usefully described by primary tastes" (p. 631).

It is our purpose in this article to review the history of the development of the concept of taste qualities and to discuss the theoretical issues involved in relating the psychophysical and physiological approaches to understanding sensory coding in taste. We argue that the four taste qualities together exhaust the qualities of taste experience. We propose further that the four taste qualities, far from being arbitrary, may profitably be thought of as representing separate but interacting sensory systems in the same way that we think of the skin senses. Although the focus of the article is on the status of the qualities of taste, it is necessary to discuss the related issues of the nature of the stimulus dimension(s) for taste and the physiological mechanisms that code the dimension(s). The two major positions of sensory coding in taste are known as the labelled line theory and the across-fiber pattern theory. The labelled line theory holds that the quality information is carried by the fiber that is most responsive to a particular stimulus, whereas the pattern theory holds that the information consists in the relative firing rate of two or more fibers.

This research was supported by National Institutes of Health Grant 2 RO1 NS 07873. We thank L. M. Bartoshuk and L. E. Marks for helpful discussions.

Requests for reprints should be sent to D. H. McBurney, Department of Psychology, University of Pittsburgh, Pittsburgh, Pennsylvania 15260.

Furthermore, the question of whether taste is analytic or synthetic in the way it responds to mixtures has become an issue in the debate over gustatory sensory coding. We argue that the question of the status of the four taste qualities is independent of the resolution of both the analytic–synthetic debate and the labelled line versus pattern theory debate.

It is necessary at this point to define taste, for the purpose of this article, as those sensations mediated by the taste buds. As such, the sense of taste is part of a perceptual system that involves all of the chemically sensitive nerves and end organs of the oral and nasal cavities that aid in the investigation of the chemical environment (cf. Gibson, 1966). Thus, taste is distinguished from flavor, which comprises other sensations mediated by olfaction, touch, temperature, and even vision. The distinction between taste and flavor has formed the basis of the vast bulk of the work in taste and is crucial to the understanding of the logical status of the taste qualities.

Relation of Psychophysical Data to Physiological Data

A fundamental problem in the analysis of a sensory system is to relate physiological and psychophysical data, that is, to develop what Brindley (1960) called *linking hypotheses:* "If a physiological hypothesis, i.e. a hypothesis about function that is stated in physical, chemical and anatomical terms, is to imply a given result for a sensory experiment, the background of theory assumed in conjunction with it must be enlarged to include hypotheses containing psychological terms as well as physiochemical and anatomical" (p. 145) ones.

The problem in taste research is that there is, at present, little agreement on the status of the psychological terms that are presumably to be explained by the physiological data by the way of linking hypotheses. Although some may wish not to be constrained by the categories of human taste experience, it is certainly true that terms like sweet and salty, which are unquestionably derived from human experience, are used in taste physiology in ways that appear definitive. Are the taste qualities primaries and, if so, in what sense of the word? Are they arbitrary terms borrowed in a naive way from our language? Or, are they simply arbitrary locations in a multidimensional perceptual space?

Uses of the Term Primary

The psychological distinctiveness of sweet, salty, sour, and bitter has tempted many to label these qualities *primary*. The term *primary* appears to have been borrowed from vision, and its application to any other sensory system unavoidably invites comparison with color perception. The term can be a source of confusion because it is used in a number of different ways. It is used variously to refer to (a) sensations that are psychologically (phenomenologically) distinct and that cannot be analyzed introspectively into two or more categories, such as the color yellow; (b) stimuli that may be mixed to produce sensations that are normally associated with a third stimulus, as with the visual mixture primaries (it should be noted that the primaries in this usage are not unique in the case of vision; there are a large number of possible mixture primaries); (c) stimuli that are the best exemplars of some sensation, such as NaCl for salty or 585 nanometers for yellow; (d) receptors, neurons, or neural mechanisms that are especially sensitive to a particular stimulus. This last usage often implies a one-to-one correspondence between two or more of the meanings of the term *primary,* for example, primary stimulus – primary neural element – primary sensation. It will be recognized that this sort of isomorphism does not hold in the case of vision. The mixture primaries need not be psychologically primary; the receptor primaries are not the same as the sensation primaries, and the neural primaries are still different. It is little wonder that workers in vision tend to eschew the use of the term *primary* altogether.

The related problems of primaries and psychophysical linking hypotheses are illustrated by Frey's (cited in Melzack & Wall, 1962)

theory of cutaneous sensory coding. As Melzack and Wall pointed out, Frey's theory involves a number of assumptions: (a) that there is a one-to-one correspondence between dimensions of sensory experience and types of receivers in the brain; (b) that there are distinct afferent nerves; (c) that there are distinct receptors in the skin; and (d) that there are distinct stimulus dimensions that subserve the dimensions of sensory experience. The same assumptions are often made in discussions of taste primaries. However, the naive notion of a direct correspondence between levels of processing need not hold for the notion of psychological primaries (the first usage of the term mentioned earlier) to be valid. We prefer the term *basic* taste to *primary* taste because it is used unambiguously to refer to the sensation.

Problems of Gustatory Sensory Coding

There are at least three separate problems to solve before it can be said that we have achieved a theory of sensory coding in taste: (a) the nature of the sensations, (b) the nature of the stimulus dimension(s), and (c) the physiological mechanisms that subserve the coding of the sensations. Each of these is discussed below. As one will see, the analysis of taste sensation has had a longer historical development than that of the other two problems. Our knowledge of the physiological mechanisms involved in the coding process and of the nature of the stimulus dimensions is far from complete. Therefore, one is forced to start with the sensory analysis and work backward to the stimulus to achieve a theory of sensory coding. This process involves what Boynton and Onley (1962) called a *converse linking hypothesis,* that is, inferring stimulus or neural events from sensation rather than the reverse. As Boynton and Onley pointed out, it is much more tenuous to conclude that a particular converse linking hypothesis is true, because many different stimuli can give rise to the same response, whereas the same stimulus (or the same neural activity) should always give rise to the same sensation.

Much of the psychophysical and physiological taste research has involved the converse linking hypothesis either implicitly or explicitly. Thus, the position taken with respect to the nature of taste sensations has an important practical impact on the approach to the investigation of stimulus dimensions and physiological mechanisms. For example, the systematic search for similarities among a large group of stimuli that all give rise to the same taste quality rests on the assumption that there are a limited number (e.g., four) of discrete taste qualities. Birch (1976), for example, reviewed the correlation between the molecular structure of sugars and the intensity of their sweet taste. And similarly, Dastoli and Price (1966) extracted "sweet-sensitive" proteins from the bovine tongue. The choice of exemplars of salty, sour, sweet, and bitter stimuli in almost all psychophysical and physiological research usually rests on the assumpution that these four qualities *are* the taste sensations. On the other hand, by assuming the continuous nature of taste sensations, Schiffman and Erickson (1971) found that taste stimuli formed a multidimensional space that they believed to be incompatible with four basic qualities.

Historical Development of Taste Categories

The origins of the current views on the nature of taste qualities may be found in the historical development of the psychological sensation categories and their relationship to the taste system as it was known prior to electrophysiological recording. Our summary of some of the historical aspects of the taste system is based largely on Bartoshuk's (1978) review of the history of taste.

The naming and categorization of taste sensations date back to the Greeks. Aristotle (384–322 B.C.), for example, listed seven basic tastes: sweet, bitter, sour, salty, astringent, pungent, and harsh. Between the time of the Greeks and the 19th century, the number of taste sensations described as *basic* varied among the seven named by Aristotle, the eleven by Haller (in 1786), an unlimited number by Rudolphi (in 1823), the six by Wundt (in 1880), the five by Öhrwall (in 1891), and the four by Kiesow (in 1896). During the 1800s the investigation of the

anatomy of the taste system prompted the elimination of some previously named basic tastes as actually being the result of olfaction or touch (Bartoshuk, 1978; Öhrwall, 1891; Skramlik, 1926). Thus, by the early 1900s salty, sour, sweet, and bitter were generally agreed upon as basic tastes with alkaline or insipid often also included.

Classical Bases for the Four Taste Qualities

The basic taste qualities were arrived at largely by introspective analysis, but other evidence was used to support their existence. One justification for the four qualities considered was the adaptiveness of the association between the various taste qualities and the nutritive or poisonous characteristics of chemical substances. For example, salt for some animals is a vitally important and scarce nutrient; for others the problem may be to avoid the osmotic consequences of high salinity (Dethier, 1977). Sweet is correlated with high calorie substances, bitter with poisons, and sour with corrosive substances. In fact, analysis of taste stimuli suggests broad and reasonably powerful predictive validity for the taste qualities, particularly between sourness and the H^+ ion, but also between sweetness and carbohydrates, bitterness and alkaloids, and saltiness and alkali halide salts. Other evidence for four qualities was the work showing the differential sensitivity to the four qualities across the tongue (cf. Boring, 1942; Hanig, 1901); the selective disappearance of quality sensitivity following the application of topical anesthetics (Bartoshuk, 1978; Kiesow, 1894b); the selective modification of taste quality following gustatory contact with certain plant substances—*Gymnema sylvestre* and *Synsepalum dulcificum* (Kiesow, 1894b; Shore, 1892; Skramlik, 1926); and the lack of synthetic effects of taste mixtures (Kiesow, 1894a, 1896).

Modality Versus Quality

By the turn of the century the number of the basic tastes was generally agreed upon, but agreement did not exist as to the nature of these taste categories. The views of Helmholtz (1879/1968) on perception in general and his distinction between sensory qualities and sensory modalities in particular had a great influence on those who were to begin the debate on the nature of basic tastes nearly a quarter of a century later. Helmholtz classified sensations as belonging to separate *modalities* if there were no transitions between them; for example, "blue, sweet, warm, and the pitch of tones" (p. 210) belong to separate modalities. The term *quality* was applied to different perceptions within the same sense; for example, blue and violet would be two qualities within color vision.

The modality–quality distinction was applied to taste, and the debate began. On one side were those who thought of salty, sour, sweet, and bitter as four qualities within one sense; the alternative view was that the four basic tastes actually represent four separate sensory modalities. Kiesow, a student of Wundt, was one of many who thought of the four basic tastes as qualities. He went further, however, and proposed a theory to relate these qualities that was based on an analogy to the opponent-process theory of color vision proposed by Hering, with whom he was personally acquainted (Murchison, 1930). Hering's theory was based on his observations of the simultaneous contrast exhibited by the primary visual hues of red and yellow or blue and green. It was Kiesow's view that the qualities salty, sour, sweet, and bitter are actually the four taste "primaries." However, he had only moderate success in demonstrating simultaneous and successive contrast in taste (Kiesow, 1894a, 1896). Öhrwall (1891, 1901), on the other hand, argued that there was no "transition" to be found among any of the four basic tastes and that they were, therefore, four separate modalities. Contrary to Kiesow, he maintained that the phenomena of simultaneous contrast and successive contrast did not exist in taste. Öhrwall criticized Kiesow's taste theory analogy with color vision as faulty, but Kiesow's view that the four tastes are primary qualities prevailed.

Research on the response of the taste system to a mixture of two or more sapid sub-

stances does not support these analogies to color vision. First, no new qualities are produced by a taste mixture, which strongly suggests that taste sensations are limited (Bartoshuk, 1975). That is, a mixture of NaCl and HCl will taste salty and sour but never sweet and/or bitter and/or something else. There is no gustatory analogue to orange. Second, it is not possible to produce a tasteless mixture by an appropriate combination of components, unless the components are themselves so weak as to be nearly tasteless. Thus, there is no gustatory analogue to gray. On these bases, taste has been considered an analytic sense rather than a synthetic sense.

Most researchers preferred to think of salty, sour, sweet, and bitter as four qualities as opposed to the stronger view that they are four separate modalities. However, there was still disagreement among those supporting the more popular *quality* view as to the relationship among those qualities. Applying the label *primary* to each quality and making analogies with theories of color vision dominated and continue to dominate most theories of taste. For example, in the early part of the 20th century, Henning (1927) suggested that the relationships between the four basic tastes could be represented by a hollow tetrahedron. By placing salty, sour, sweet, and bitter on the corners, all other tastes could be placed either along the continuum between two tastes (e.g., on the salty–bitter edge) or on the surface formed by three basic tastes. Thus, all tastes could be represented as appropriate mixtures of two or three of the four "primaries." Representing a much less popular alternative to the primary qualities – color vision analogy, Hahn (1934; Hahn, Kuckulies, & Bissar, 1940; Hahn, Kuckulies, & Taeger, 1938; Hahn & Ulbrich, 1948) argued that salty, sour, sweet, and bitter (and alkaline) are independent qualities (Bartoshuk, 1978). Hahn based his views on his work in adaptation and cross-adaptation and their effects on taste thresholds.

Although there was disagreement on whether the taste system operates like color vision, descriptions of the relationships among different tastes rested on some variation of Müller's influential "doctrine of specific nerve energies" (cited in Boring, 1950). The general assumption was that there is a simple, if unspecified, correspondence between some physical attribute of the stimulus, the operation of the nerve, and the sensation produced. With the development of techniques for recording the electrical activity of single nerve fibers, the search for neural correlates of the human taste experience was broadened to other mammalian nervous systems. Although the historical psychophysical data suggested a search for specific salty, sour, sweet, and bitter fibers, Pfaffmann's (1941) finding that the four basic tastes were not mediated by specific fibers created a problem that is still with us today.

Modern Search for Taste Qualities

With the advent of the vacuum tube and the subsequent development of gustatory electrophysiology, it became apparent that no neat correspondence exists between taste qualities and individual taste nerve fibers (Pfaffmann, 1941). One of the results of this failure of the straightforward extension of the doctrine of specific nerve energies has been to intensify the sort of theorizing typified by Kiesow (1894a, 1894b, 1896), which makes use of the analogy of the senses. It is inevitable that such comparisons be made, and, of course, they are beneficial to the extent that the various senses display common mechanisms of neural functioning. As one sees below, the analogy of the senses has been used to raise a number of objections to the four taste qualities.

Cultural Relativity Objection

The first objection is the notion that the taste qualities are culture bound; that is, if one were to study other cultures, or to throw away the usual categories and start from scratch, one might end up with a completely different set of taste categories. Perhaps. But the best example we have of such a possibility is the number of names for snow em-

ployed by Eskimos. However, this example is not very pertinent because, with some training, any person could discriminate the bases for the distinctions among the names. Studies of non-Western cultures (Chamberlain, 1903; Myers, 1904) find that various languages often lack specific names for one or more of the four taste qualities. Even though one or more of the four may be lacking, one does not seem to find cultures that make more distinctions than the four basic tastes that cannot be explained as describing flavor as opposed to taste, for example, astringent. Recently it has been found that Malay speakers use the same taste words as English speakers but tend to use more modifying adjectives (O'Mahony & Muhiudeen, 1977). There is, of course, a parallel controversy in color vision (e.g., Bornstein, 1973). Heider (1972) studied recognition memory and learning of associations to focal and nonfocal colors by New Guinea Dani, who lack names for hues in their language. (Focal colors are those that best exemplify common color names, e.g., red, orange, yellow, etc.) She found that the Dani made fewer errors in recognition of focal compared to nonfocal colors and learned associations to focal colors faster than to nonfocal colors. Heider also found that native speakers of all language families used shorter words or phrases to describe focal colors than to describe nonfocal colors. Heider's experiments show that the effect of language on perceptual categorization has been overstated, at least for hues. In the absence of similar work in taste, Heider's data imply that taste names are unlikely to be influenced greatly by language. The weight of evidence favors the notion that the lack of comparable names for certain colors in various cultures has a basis in the relative lack of utility of these names in primitive cultures (Woodworth, 1910) rather than in a fundamentally different way of perceiving.

Multidimensional Space Objection

Similar to the cultural relativity objection is the suggestion made by Frings (1948) that "the primary modalities of taste might . . . be simply points of familiarity in an unbroken series of stimulative values. . . . The work of Pfaffmann on electrical impulses from tastebuds, although not fully explicable by this hypothesis, is certainly more nearly explained by it than by the hypothesis of primary modalities" (p. 32). This suggestion makes explicit the notion of a continuum, although none has been identified. Erickson and his co-workers have followed in the direction suggested by Frings (cf. Doetsch, Ganchrow, Nelson, & Erickson, 1969; Erickson, 1963, 1967, 1968; Erickson, Doetsch, & Marshall, 1965; Erickson & Schiffman, 1975). What Erickson and his co-workers were looking for was a taste "wavelength" that would permit an isomorphic correspondence among the chemical, neural, and psychological processes. "Stimuli which are proximate in a multidimensional space on the basis of the similarity of the neural inputs [in terms of across-fiber patterns] are also similar in terms of psychophysical judgments" (Schiffman & Erickson, 1971, p. 632). Erickson et al. (1965) attempted to find an isomorphism between the neural and the chemical domains. They asked, "Is it possible to derive the NRFs [neural response function, i.e., "some measure of the neural activity as a function of a stimulus dimension" (p. 262)] for taste without knowledge of the relevant stimulus dimensions? Further, is it possible to discover the stimulus dimensions? Data presented . . . show that the NRFs and stimulus dimensions for taste may be determined" (pp. 248–249). But even though it might be argued for vision that a sort of isomorphism exists among the stimulus, receptor, neural, and psychological levels, it is a rather rubbery isomorphism that involves, among other things, a shift from three types of receptors to two types of opponent-process neural elements. It is true that the spectrum is preserved through all of these levels but not isomorphically with respect to the number of mechanisms involved. It seems better in the case of vision to postulate something other than a strict isomorphism as a linking hypothesis.

Schiffman and Erickson (1971) have proposed a model for gustatory quality that is

based on multidimensional scaling of taste stimuli. They presented a large number of solutions to subjects who scaled them for similarity and on a number of semantic dimensions. They derived a taste space from this procedure that, they argued, does not support the notion of taste primaries. There are several problems in accepting this conclusion, problems with the experimental method, problems with the multidimensional scaling, and problems in interpretation.

First, and fundamental to the whole argument of their article, they did not take adequate precautions to assure that they stimulated only the sense of taste, as it is usually defined for psychological purposes, namely, taste bud stimulation. Their subjects wore nose plugs "to reduce olfactory input," but this is not sufficient to eliminate the sense of smell. A better procedure would have been to use the technique of forcing a gentle stream of air into the nostrils (Mozell, Smith, Smith, Sullivan, & Swender, 1969), thereby preventing the reflux of odorous air into the nasal cavity. This is a curious procedural deficiency, since the purpose of the experiment was to determine the dimensionality of a taste space. Any contribution from the sense of smell seriously distorts the taste space. This weakness is particularly significant considering that the history of taste qualities shows a trend toward a decrease in the number of taste qualities as a result of increasing care in eliminating sensations mediated by other sensory systems. It was such careful psychophysical work that ruled out the alkaline and metallic tastes many years ago. Skramlik (1926) reviewed work by Frey and Herlitzka that showed clearly that the alkaline and metallic tastes resulted from olfactory sensations and disappeared when these were excluded. Another standard method of determining whether a sensation quality can be attributed to taste is to place the substance on parts of the tongue, such as the center, that are known to be devoid of taste buds. Such observations may well have obviated discussion of other nontaste qualities like *bitey, burning,* and *tingling.* Skramlik's review demonstrates clearly that the earlier workers were keenly aware of these problems in the psychological analysis of taste qualities.

The scaling problem in the Schiffman and Erickson (1971) experiment is inherent in the use of multidimensional scaling. Although multidimensional scaling has been used a great deal with considerable impact in certain areas, it may fairly be said that its contribution to sensory processes has not been the discovery of unknown dimensions as much as the improvement of our understanding of the metric relationships among known dimensions. Further, multidimensional scaling is extremely sensitive to the choice of stimuli to be scaled. If most of the stimuli are very similar to one another, one sort of dimensionality will result. If a single stimulus is added that is very different from all of the other stimuli in the sample, an entirely new dimension will emerge as a result. For this reason, scaling of a small subset of stimuli often gives fundamentally different results from the scaling of the entire set. This is particularly true in smell (e.g., Schiffman, 1974) and taste (e.g., Gregson, 1966). In addition, different multidimensional scaling methods often give different results. This can be seen in the data of Schiffman and Erickson (1971), in which the scaling based on similarity led to three dimensions and the scaling based on the semantic differential data gave two. Schiffman and Erickson chose to accept the similarity data for the space, but they interpreted the dimensions by means of semantic differential scales. On this basis they came up with the following three dimensions: molecular weight, hedonic, and deviation of pH from neutrality. Keeping in mind that the method of stimulus presentation and the scaling technique are both weak, the interpretation of the space presents problems. First, one of the dimensions, hedonic, is a purely psychological dimension. The other two, pH and molecular weight, are purely physical. Second, these dimensions are not orthogonal; hedonic is correlated with molecular weight. In addition, there are some large inconsistencies in the locations of stimuli along the molecular weight dimension. It is difficult to see how such a space could be useful in devising linking hy-

potheses about the coding of taste qualities. In any case, it is fair to say that the four taste qualities fall into four clusters in their space. It appears that the data would be at least as well described by the four traditional taste qualities, with those that fall outside of the space defined by the four qualities representing, in part, extragustatory (e.g., smell) sensation. What Schiffman and Erickson have achieved is a description of a psychological taste space that neither supports nor denies the existence of four basic tastes.

To return to the problem of interpretation of the multidimensional scaling data, consider the multidimensional scaling of colors (cf. Schiffman & Erickson, 1971), which to date has accomplished the validation of the Munsell color space. Although this is an achievement in its own right, it in no way constitutes a theory of sensory coding, in and of itself, because it is simply a description of the psychophysical relationships among the colors in terms of the physical stimulus.

Multidimensional scaling of stimuli presented to different senses has been performed. For example, Wicker (1968) had subjects rate the similarities between pairs of tones, Munsell color chips, or tones and chips in an effort to study synesthetic relationships among these two stimulus domains. He found that a single multidimensional space accounted well for both the colors and the tones. Other intersensory interactions are well-known, as the literature on auditory–visual synesthesia demonstrates (e.g., Marks, 1975). Although not all people experience synesthesia, and it may seem somewhat artificial to some, nonsynesthetes relate color dimensions to auditory dimensions in the same way as synesthetes; that is, subjects are very willing to relate sensations from systems that are undeniably distinct. Nafe (1927), using introspection, analyzed the qualities of the sensations mediated by the skin senses. He concluded "that the 'qualities' of felt experience . . . are analyzable patterns of experience . . . that such experiences vary in brightness, volume, density, and definiteness of outline" (p. 398). Had Nafe been working 50 years later he might have done his experiment using multidimensional scaling. The results he did obtain using the best techniques of his day are consistent with our conclusion that multidimensional scaling does not necessarily yield the underlying sensory dimensions. In fact, multidimensional scaling is often done on very diverse stimuli. The dimensions derived are not taken to represent any physical relationship among the stimuli. For example, in scaling animals, dimensions such as fierceness have been obtained (Henley, 1969). These are not interpreted as physical dimensions or taxonomic classifications (cf. Martindale & Hines, 1975). In addition, various interactions among the various senses are well-known. For example, cold and warm seem to be different sensory systems as far as their anatomy and physiology are concerned, even though their perceptual unity could be argued. Nevertheless, they obviously interact to a great extent, and their interaction may even be responsible for the sensation of heat.

Therefore, little seems to be gained from the multidimensional analysis of taste experience as far as the question of the nature of the taste qualities is concerned. It follows that an isomorphism between the stimulus and the sensation is not the only, or even the best, conclusion to draw from multidimensional scaling of sensation.

Recent Evidence for the Four Qualities

Modern research has made much use of the four taste qualities, but more out of convenience than out of conviction that they are basic. For example, Bartoshuk (1974) wrote, "In light of this [controversy over whether these taste qualities are primaries], some investigators have come to follow a somewhat different strategy in studying taste quality. Instead of concentrating on finding all primaries, they have turned to studying the functional properties of sweet, sour, salty and bitter" (p. 279). Even so, evidence for the limited number of taste categories comes from recent psychophysical studies of the effects of the following: cross-adaptation, water taste, drugs, taste-altering substances (*Gymnema sylvestre* and miracle fruit), mixtures, and spatial and temporal properties. It is true that taken alone these data have a

certain circularity about them as evidence for the four basic tastes. The four taste qualities were used as response categories and may be seen as forcing the data in the direction of evidence for basic tastes. It should be noted, however, that subjects in some of the experiments discussed below were given the opportunity to use additional categories to describe their taste sensations, but did not do so with any regularity (e.g., Bartoshuk, McBurney, & Pfaffmann, 1964). The point we wish to emphasize is that the four taste qualities are both necessary and sufficient to account for the qualitative and quantitative differences in the psychophysical data.

Cross-Adaptation

Psychophysical studies of the response of the taste system to one stimulus following adaptation to another support the limited number of taste sensations. It is true that this work on cross-adaptation could not have been done without having the subjects report on the taste qualities of the compounds. But it is clear that the effect of adaptation is to eliminate or substantially reduce the response to the quality to which the tongue has been adapted, whatever its name. Where the cross-adaptation was between stimuli sharing the same quality, the following results were reported: (a) Sucrose adaptation reliably reduced the sweetness of all sweet-tasting compounds tested (McBurney, 1972); (b) adaptation to NaCl reduced the saltiness of every salt tested (Smith & McBurney, 1969); (c) adaptation to citric acid reliably reduced the sourness of all other acids tested (McBurney, Smith, & Shick, 1972); and (d) the results for bitter were not as clear-cut, since adaptation to quinine HCl reduced the bitterness of some bitter compounds without affecting others (McBurney et al., 1972).

The psychophysical data on cross-adaptation have implications for the number of receptor mechanisms that must operate in the taste system. The effects of cross-adaptation are found to a greater or lesser extent in all four qualities, and there is little across-quality adaptation, thus implying the operation of separate receptor mechanisms. The data do not prove the existence of specific receptor sites, but they do imply that there are a limited number of receptor mechanisms. For example, it is likely that a single receptor mechanism codes the sweet taste, another codes saltiness, and a third codes sourness. The mechanism for bitterness, however, is more complex.

Water Taste

The water taste phenomenon, that is, the taste of water after adaptation to a compound, also supports the limited number of taste sensations. Each of the four qualities and no others have been produced as water tastes after suitable adaptation (Bartoshuk, 1968; McBurney, 1969; McBurney & Bartoshuk, 1972; McBurney & Shick, 1971). It should be noted that the water taste phenomenon cannot be explained by a simple opponent process. For example, adaptation to NaCl will cause water to have a bitter or sour–bitter taste; bitter and sour substances induce a sweet water taste; sweet substances produce a sour or bitter water taste; and salty water tastes have only been reliably produced by urea and closely related compounds. Apparent cross-enhancement between qualities was found in some studies that used the cross-adaptation paradigm. However, the increase in the perceived intensity of a stimulus after adaptation was shown to be explained by the water taste phenomenon (McBurney & Bartoshuk, 1973). The increase was always in the quality normally produced as a water taste rather than in the dominant quality of the compounds.

Taste-Altering Substances

The specificity of the effects of two taste-altering substances, found in *Gymnema sylvestre* and *Synsepalum dulcificum* (miracle fruit), has provided information about the nature of taste sensations and possible taste receptor mechanisms. The replication and extension of some of the historical work on the effects of chewing *Gymnema sylvestre* showed that only the sensation of sweet is abolished, including the sweet water taste

(Bartoshuk, Dateo, Vandenbelt, Buttrick, & Long, 1969). Since stimuli that elicit a single taste quality (sweet) are all influenced in the same way by *Gymnema sylvestre,* the implication is that the taste quality of sweetness is distinct from the other qualities. There is also the implication that there is a single receptor mechanism that codes the sweet taste and that the gymnemic acid operates by competing with sweet compounds for the sweet receptor sites. Miracle fruit is a berry that, when chewed, causes sour substances to taste sweet. The effect of this taste modifier can be explained by analyzing its effect on the particular qualities of sour and sweet. K. Kurihara (1971) and K. Kurihara, Y. Kurihara, and Beidler (1969) suggested that the action of miracle fruit is a result of the interaction on the taste cell membrane between the acid of a normally sour substance and the glycoprotein that is the active ingredient in the fruit. They suggested that the glycoprotein does not itself normally stimulate any receptor sites but that the presence of acid causes a change in the shape of the membrane in such a way as to cause contact between the glycoprotein and sweet sites. Thus, it is possible to understand the sweetening effect as the addition of a new taste (sweet) and the lack of increase in total intensity as a case of mixture suppression of sour by sweet (Bartoshuk, 1975).

Effect of Locus

A reexamination of the variation in sensitivity over the tongue has produced evidence for quality specificity and some insight into the complexity of the receptor mechanisms that operate in the taste system. Collings' (1974) investigation of the effect of locus of stimulation on taste threshold generally confirms Hanig's (1901) data on the differential sensitivity of the tongue and supports the distinctiveness of the taste sensations. The exception she found was that sensitivity to bitter was greater at the front of the tongue than at any other tongue locus, not at the back as Hanig reported.

Stevens (1969) argued that the exponent of the power function that relates sensation magnitude to stimulus concentration is principally determined by the characteristics of the receptor system. (Even though fairly consistent differences are found among the exponents for the four qualities [Meiselman, 1972], we have not used this as evidence for basic tastes. The exponent is sensitive to several variables in addition to quality, namely, method of stimulation; range of stimuli; psychophysical method; presence, value, and location of standard; and so on [Stevens, 1975]. Furthermore, the exponents have never been determined with the exactness that would justify making a strong case on this basis.) Evidence for the distinctness of receptor mechanisms for taste qualities comes from the fact that, in general, locus of stimulation also has a differential effect on the psychophysical function that relates sensation to stimulus concentration, both between qualities and within one quality (Collings, 1974). The differences Collings found between qualities are compatible with the existence of four distinct sensations, but the differences she found across loci within qualities imply a complex receptor mechanism that is difficult to explain. Because Smith (1971) showed that varying the number of receptors stimulated (at the front of the tongue) does not change the psychophysical function for a given taste compound, Collings concluded that the observed differences in threshold were not simply the result of differences in the number of particular receptors present at each location.

Temporal Properties

Another aspect of taste that has been studied is the temporal properties of the gustatory system (cf. McBurney, 1976). Early research (1914–1955) on the temporal response of the taste system falls into four areas: reaction time (Bujas, 1935; Piéron, 1914), growth of sensation (Bujas & Ostojcic, 1939), relationship between time and intensity (Bujas, 1934; Hara, 1955), and rate of adaptation (Bujas, 1953; Hahn, 1949). The first three areas are closely related, and the early research indicates that

the temporal response of the system varies according to the quality (e.g., salty, sour, sweet, or bitter) of the stimulus. In particular, reaction times to a stimulus were found to be a hyperbolic function of intensity and varied among qualities in increasing order from salty, sour, and sweet to bitter. A similar ordering was found to hold for growth of sensation. Results concerning rate of adaptation are not so clear. Problems with the methods used to measure rate of adaptation and questions concerning the existence of complete adaptation prompted the search for another technique for studying temporal properties.

The most recent psychophysical method of investigating the nature of taste qualities is the application of the techniques of linear systems analysis to the gustatory system. Work such as this has been going on for some time in vision (e.g., Sekuler, 1974). In our laboratory we attempted to investigate the temporal properties of the taste system (McBurney, 1976). Briefly, linear systems techniques can be used to study the input–output relationships of a linear system. By finding the ratio of a sinusoidally varying input to the output across a range of frequencies, a transfer function can be calculated that is characteristic of the temporal properties of the system. Extension of this technique to the gustatory system was made by presenting the tongue with a solution of sinusoidally varying concentration. The output studied was the threshold for several frequencies of stimulus presentation. A temporal-modulation sensitivity function was obtained for each of the four qualities. Our results agree with the earlier data in that the ordering of the sensitivities of the four qualities as represented by the sensitivity functions was as follows: salty, sweet, sour, and bitter. These functions differentiated among qualities and therefore imply that the functions represent temporal characteristics of four separate systems.

Inner Psychophysics of Taste

Because the approach of this article has been psychophysical, it is appropriate here to point out a distinction made over 100 years ago by the founder of psychophysics, G. T. Fechner—that between outer and inner psychophysics (Howes & Boring, 1966). Outer psychophysics is the familiar enterprise of relating sensation to external stimulus. Inner psychophysics is the relationship of sensation to the physiology of the nervous system. Of course in Fechner's day this was only a far-off dream, but we have made some progress along these lines in recent years. The purpose of this section is to review the inner psychophysics of taste, the relationship of the physiological data on neural mechanisms (receptor sites, cells, and fibers) to the existence of taste qualities. We discuss the implications these data may have for linking hypotheses concerning the neural coding of taste quality.

Receptor Sites

The nature of the receptor site(s) for taste is still poorly understood. However, Beidler (1971) has determined that NaCl and sucrose each bind to one receptor site and that KCl, NH_4Cl, and other salts that do not have pure salty tastes bind to more than one site. Such a finding is consistent with the position that the four qualities are basic tastes. If the taste of NaCl were but one of many tastes located along a single taste dimension, then one might expect every substance to stimulate a separate site or expect NaCl or sucrose, for example, to stimulate more than one.

Neural Coding of Quality

Pfaffmann, in his classic study (1941), and all subsequent investigators that used vertebrate subjects found that single taste neurons typically respond to stimuli representative of more than one taste quality. As a result, Pfaffmann (1959a, 1959b) proposed that the sensory code for taste quality is carried by the relative firing rate of two or more fibers. This hypothesis linking the nonspecific neurons to specific sensations has been called the across-fiber pattern theory. Zotterman (1959), on the other hand, emphasized that each fiber typically has a stim-

ulus to which it responds best and argued that the activity in each fiber signals the quality of its best stimulus. This position has come to be known as the labelled line theory. The difference between the two hypotheses has not yet been resolved, since the weight of experimental evidence does not clearly favor the across-fiber pattern or the labelled line.

For example, Frank (1973) recorded from the chorda tympani of the hamster and found the same sort of broad tuning that was found by Pfaffmann in the rat. However, she discovered that if the stimuli were arranged in the order sweet, salty, sour, bitter, there was always one maximum of responding, with responsiveness decreasing monotonically on either side of the maximum. Thus, instead of the responsiveness of the neurons to various qualities that appear to be random, there was some orderliness for the first time since the beginning of electrophysiological study of taste neurons. Frank pointed out that the order of stimuli that produces the simplification of the profiles happens to be from acceptance to rejection. This is a curious finding and may simply be fortuitous. However, Frank's results have led to a renewed interest in the idea that the sensory code may be contained in a single neuron, or in the labelled line, as it has come to be called.

Comparison of Psychological and Psychophysical Data Relative to Coding

Direct comparisons of neural and psychophysical responses in the human are obviously limited to special circumstances, but such studies have been done. Electrophysiological responses of the exposed chorda tympani nerve of otosclerotic patients were found to be closely correlated with their magnitude estimates of the intensity of various sweet stimuli. Also, the neural as well as the psychophysical response to sweet stimuli was abolished following the application of *Gymnema sylvestre*. In addition, it was found that the time required for complete adaptation to NaCl agreed with the psychophysical reports (Borg, Diamant, Oakley, Strom, & Zotterman, 1967; Diamant, Oakley, Strom, Wells, & Zotterman, 1965).

The electrophysiological investigation of the effects of cross-adaptation has produced data that are remarkably similar to those from the psychophysical studies mentioned above. Smith and Frank (1972) studied cross-adaptation betwen salts in the rat chorda tympani and found that the transient response to a salt was affected by adaptation to other salts. They compared the amount of cross-adaptation they obtained with that obtained by Smith and McBurney (1969) for those pairs of stimuli that were common to the two experiments. The degree of cross-adaptation observed was very similar in the two studies. In addition, it was found in both studies that salts with common cations cross adapted more than did salts with different cations. The implication of these two studies is the same, namely, that there is a common neural mechanism for saltiness. As discussed earlier, this does not necessarily imply that separate receptor sites or fiber types exist. In fact, the data of Smith and Frank (1972) are very similar to the correlations obtained by Erickson et al. (1965) from the responses of individual rat chorda tympani fibers to pairs of salts and are thus equally compatible with an across-fiber pattern theory of quality coding.

The most determined attempt to extend Pfaffmann's across-fiber pattern theory has been made by Erickson. From the relative responsiveness of each neuron to pairs of salts, Erickson et al. (1965) derived what they termed a *neural response function* (NRF) for each neuron that described its sensitivity to many salts and that allowed them to order the salts as if they fell along a continuous dimension. They reasoned that the NRFs for gustatory neurons were similar to the relative activity of visual neurons in response to the visual spectrum. The crucial assumption of Erickson's approach to taste coding is the existence of a continuous stimulus dimension, and all of Erickson's hypotheses about sensory coding are based on this assumption. It is because of this assumption that the NRF work suffers from the same weakness as the multidimensional scaling work described

earlier. Specifically, it relies on a converse linking hypothesis, in this case a converse physiological–physical linking hypothesis. Erickson attempted to find the stimulus dimension from an analysis of the relationships among the physiological responses. Such an approach will lead to a solution, but other interpretations of the results of the NRF work are possible. For example, one could do the physiological equivalent of the multidimensional scaling of cutaneous stimuli discussed above as a thought experiment. This time consider establishing NRFs for many stimuli presented to the chorda tympani nerve, which subserves touch and temperature as well as taste. It is likely that NRFs could be established for these stimuli and that one could develop some sort of space based on them. However, it would not demonstrate the existence of a physical stimulus dimension that underlies all of the various stimuli.

The Analytic–Synthetic Distinction and Coding Theory

Erickson's work was a very creative extension of Pfaffmann's approach to taste coding, and one of its most important contributions was to make explicit a number of hypotheses about sensory coding. However, it is clear that there are difficulties created by the assumption of a single stimulus dimension, as, for example, in Erickson's explicit hypothesis about the coding of taste mixtures. Erickson (1968) claimed that synthetic systems are coded by across-fiber patterns and analytic systems by specific fibers. On this basis, taste must be a synthetic system in spite of the fact that the qualities of the components in a mixture are not fused or otherwise lost and that no new qualities are produced. It is true that color vision is both synthetic and has a pattern theory of coding. But, audition is clearly analytic, and the auditory nerve displays fairly broad tuning at the level of the first-order neuron (Kiang & Moxon, 1974). Relatively specific firing is found only at more central levels. Therefore, the correlation Erickson proposed does not seem to hold. Erickson suggested that the mixture of two stimuli in a sense that requires a pattern theory will result in a new pattern that has a different maximum than the two original patterns and hence in a new (synthetic) sensation. One can, in fact, match a stimulus like KCl, which is salty and bitter, with a mixture of NaCl and quinine, and a subject may not be able to distinguish such a mixture from KCl. It should be noted, however, that KCl tastes salty and bitter and not something else. The "missing orange" seems a strong argument against taste being synthetic. But, the question of whether KCl is itself a mixture to begin with is actually begged. Erickson has suggested that KCl may be a mixture taste: The taste of NaCl itself could be considered a mixture taste because the stimulus solution is composed of two ionic components (Na^+ and Cl^-) that might be located at two different points along the stimulus dimension (Erickson & Schiffman, 1975). This suggetion cannot be dealt with here in detail except to say that Beidler's (1965, 1970, 1971) theory of sensory transduction in taste, which is the most widely accepted theory, considers the cation to be responsible for stimulation and the anion to be inhibitory. Further, sour, sweet, and bitter tastes cannot be similarly considered mixture tastes in this context because the stimuli are either nonionic (sweet and bitter) or the stimulation is accepted to be due to the cation (acids). This seems to create a problem for the assumption of a continuous stimulus dimension.

Two tests of the analytic–synthetic question have recently been reported. Erickson (1977) tested reaction times of subjects who had to choose between high and low concentrations of NaCl when $MgCl_2$ also varied in concentration and vice versa. He found that variation in the second compound had an effect on reaction time, being facilitating when the two covaried and inhibiting when they varied independently. However, other interpretations are possible. Total intensity of the mixture would be a relevant cue in the covarying condition and would be a distractor in the independently varying condition. Further, ignoring the overall intensity of the mixture, one has two qualities that vary independently in intensity. There are a

number of studies that suggest that an analytic sense would not necessarily code these two qualities independently. Hamlin, Stone, and Moskowitz (1955) had subjects sort cards according to shape of symbol. Performance was slower when the symbols varied in color than when they were always black. Egeth (1967) and Well (1971) reviewed other similar experiments. Although performance has not always been found to suffer in such experiments, the case made by such a design for the synthetic nature of taste is extremely tenuous. Nowlis and Frank (1977) tested the synthetic–analytic question by using the conditioned aversion paradigm (Garcia, Hankins, & Rusiniak, 1974) with rats. Rats that have been poisoned after drinking a solution will avoid that solution in a later test. If they are poisoned after drinking two solutions, one of which is familiar and one novel, they will avoid only the novel solution. In a very clever design, Nowlis and Frank made their rats sick on a mixture of NaCl and sucrose. When the sucrose was the familiar stimulus, they later avoided the NaCl as much as they avoided the mixture and did not avoid the sucrose. Results were similar when NaCl was the familiar stimulus. When neither was familiar the rats avoided both sucrose and NaCl. This is strong evidence that the rats sorted out the two components of the mixture as separate and independent tastes. Thus, Erickson's (1977) hypothesis linking across-fiber patterning to synthetic systems does not seem to hold. The evidence argues against taste being a synthetic sense.[1]

Summary

In summary, support for basic tastes in the gustatory system is found in psychophysical work, both historical and modern. First, the history of thinking on taste has shown a narrowing of the number of taste qualities to the present four on the basis of careful introspective work. Classical support for the four taste qualities also included the association between taste quality and the nutritive or poisonous nature of the chemical, the correlation between chemical structure and taste, the differential sensitivity of the four qualities across the tongue, the effects of topical anesthetics, and the lack of synthetic effects of mixtures. Recent support for the four taste qualities comes from work on cross-adaptation, water taste, taste-altering substances, the effects of locus on the threshold and on the growth of sensation with stimulus intensity, and the temporal properties of the taste system.

Electrophysiological work on taste coding began by looking for nerve fibers that would correlate with the four taste qualities. When that appeared to fail, some investigators felt compelled to abandon the concept of the four qualities as basic. However, attempts to infer the dimensionality of the stimulus and solve the sensory code for taste without making use of the four qualities have not been productive. Either of the two major positions on sensory coding in taste, labelled line or pattern theory, appears to us to be equally compatible with the existence of basic tastes. In addition, the question of the analytic or synthetic nature of taste experience seems independent of both problems, namely, basic tastes versus a multidimensional taste space and the labeled line versus the pattern theory.

What Is a Sense?

Implicit in much of the discussion so far has been the idea that taste is a single sense or sensory system. To say that the four qualities exist raises again the question of whether they might well be considered separate sensory systems. Often the four qualities have been called submodalities, implying more distinctiveness among them than is implied by

[1] After this article was written, an article by Dethier (1978) appeared that discusses the question of taste qualities from the comparative point of view. Although he does not reject the four taste qualities for man, Dethier feels that they constitute a straightjacket when applied to other animals. We freely accept that many other animals have different taste worlds. However, as argued in the present article, we believe that the behavioral and physiological work on mammals supports the substantial similarity of taste mechanisms in man and other mammals. Our main point, that taste qualities are not arbitrary conventions, is fully compatible with Dethier's position that there may be either more or fewer than four taste qualities in other organisms.

the primary color sensations but less than is implied by the difference between, say, red and F sharp. Can one imagine a smooth transition between sweet and salty or salty and bitter? We deny this and argue that they meet Helmholtz's (1879/1968) criterion for separate senses. But we must admit that there is room for difference of opinion. However, that the four taste qualities share the same receptors, neurons, and neural projections seems not to be especially important when one considers that the skin senses have a similar degree of commonality among them. We feel it may be more useful to consider taste as comprising four senses: salty, sour, sweet, and bitter. However, this is not to say that the four taste modalities are as distinct as vision is from audition. Clearly vision and audition are different sensory systems because they not only meet Helmholtz's criterion but also because they have separate receptors, neural pathways, and projections in the sensory cortex of the brain. And the skin senses, although together considered to make up the cutaneous system, are separate from each other largely because of the psychological distinctiveness of the various sensations, even though there seem to be separate receptors in some cases.

Thus, the listing of senses must remain somewhat arbitrary. The "special" senses, vision and audition, are relatively but not completely distinct (synesthesia), and the taste senses are related but not unitary.

If one must make analogies among the senses, and one must, then we argue that the proper senses with which one should compare taste are the skin senses. After all, the sense of taste shares the same receptor surface, nerves, neurons, and central projections as do the other skin senses. When one makes these analogies, one sees that the notion of four basic qualities or submodalities of taste has a great deal of empirical evidence to recommend it and avoids the pitfalls into which the analogy with vision has led us.

Tests of Significance in Stepwise Regression

Leland Wilkinson
University of Illinois at Chicago Circle

Tests of significance of the sample squared multiple correlation (R^2) in stepwise multiple regression have not been possible because its distribution is unknown. The present study used Monte Carlo simulation and least squares smoothing to construct tables of the upper 95th and 99th percentage points of the sample R^2 distribution in forward selection. A survey of published psychological research that used stepwise regression found a substantial inflation of reported significance levels when compared to the tabled values. Recommendations are given for use of these tables in evaluating results from forward selection and other stepwise methods.

Stepwise regression has a controversial role in statistical data analysis. Since the introduction of various automated techniques for selecting the "best" subset of a set of predictor variables in a multiple regression researchers have been warned about their indiscriminate use (e.g., Kupper, Stewart, & Williams, 1976; Brandt, Note 1). The primary reason for this caution is that for any subset selection procedure based on inspection of the sample data, the usual F statistic for testing the significance of the multiple correlation is biased (Pope & Webster, 1972). Unfortunately, the most widely used computer programs print this statistic at each step without any warning that it does not have the F distribution under automated stepwise selection (Armor & Couch, 1972; Barr, Goodnight, Sall, & Helwig, 1976; Dixon, 1975; Nie, Hull, Jenkins, Steinbrenner, & Bent, 1975). Researchers encouraged by a significant multiple correlation from a stepwise analysis are often surprised to find how much it shrinks under cross-validation (Schmitt, Coyle, & Rauschenberger, 1977). For one solution to this problem, the present study used Monte Carlo methods to provide tables of percentage points of the distribution of the sample stepwise squared multiple correlation (R^2) under the null hypothesis that the population multiple correlation is zero. The tabled values can be substituted directly for those on the computer printout when forward selection is used, and they can serve as approximations when other subset selection methods are used.

Distribution of the Sample R² *in Stepwise Regression*

Given a sample of size n from $k + 1$ multivariate normal variates, the sample R^2 between the first and the remaining k variates under the null hypothesis has the beta distribution. In this case, the transformation

$$F = R^2(n - k - 1)/(1 - R^2)k \quad (1)$$

has the F distribution with degrees of freedom k and $n - k - 1$. These distributions apply whether the values of the k predictors are fixed or vary across samples, as long as the null hypothesis is true.

Complications arise when k predictors are chosen from m on the basis of the sample

This research was supported by funds from the Computer Center, University of Illinois at Chicago Circle. A listing of the FORTRAN subroutines is available from the author.

Nancy Hirschberg prompted this research in a discussion of a stepwise regression analysis. Rowell Huesmann, Mike Levine, Jeremy Shefner, and Ron Golland provided valuable advice on the analysis. Bruce Korth, Jerry Dallal, and Shari Diamond commented helpfully on the present article.

data. Two straightforward cases occur, however: when $k = m$ and when $k = 1$. If $k = m$, the above distributions obviously apply. If $k = 1$, and if the predictor that maximizes the sample R^2 is chosen, then the sample R^2 has an independent beta extreme-value distribution. For this case, the F statistic in Equation 1 may be used with critical value

$$\alpha^* = 1 - (1 - \alpha)^{1/m}, \qquad (2)$$

where α is the family critical level.

Beyond these two cases, no exact distributions are known. When the subset of size k $(1 < k < m)$ is chosen to maximize the sample R^2, the distribution of the sample R^2 is an extreme-value distribution of a set of dependent beta variates. This approaches the independent extreme-value distribution when m is large and k is small asymptotically. When the predictors are correlated, this asymptotic convergence is slower, since dependencies among the sample R^2 values for all $\binom{m}{k}$ subsets are greater. Most stepwise algorithms do not necessarily maximize the sample R^2, however, and the distributions in these cases would be even more complicated whether or not the predictors were mutually independent.

Diehr and Hoflin (1974) simulated the sample R^2 distribution for the best R^2 subset among $\binom{m}{k}$ given independence among the predictors. This distribution is particularly important because its percentage points provide an upper bound on sample R^2 values from any subset selection method on independent or correlated predictors. For each $m = 2$–8, $k = 1$–m, and $n = 10, 25, 50, 100$, and 200, they computed 100 R^2 values. Each value was obtained by computing all possible regressions among $\binom{m}{k}$ and selecting the one with the largest R^2. The computing time for this task limited the number of replications and parameter values, but they were able to provide a function that approximates their Monte Carlo results:

$$R^2(k, m, n, \alpha) = w(1 - v^k), \qquad (3)$$

with w and v determined iteratively from the known values of $R^2(1, m, n, \alpha)$ and $R^2(m, m, n, \alpha)$. Furnival and Wilson (1974) developed a rapid "leaps and bounds" algorithm for computing the best subset R^2 that can be used for extending Diehr and Hoflin's results.

Rencher and Fu-Ceayong (Note 2) used Monte Carlo simulation to compute upper percentage points of the sample R^2 distribution in stepwise selection and elimination (Draper & Smith, 1966, p. 171). They generated both uncorrelated and correlated predictors for selection. As in the Diehr and Hoflin (1974) study, their results were approximations from a relatively small number of replications (200–400), but they included a wider range of parameter values.

The present study used a simple algorithm for choosing subsets: forward selection (Draper & Smith, 1966, p. 169). This method is faster than other selection procedures and exceeded many of them in a Monte Carlo study that involved several cross-validation criteria (Dempster, Schatzoff, & Wermuth, 1977). Furthermore, forward selection is the standard or most basic option in most widely used statistical programs for stepwise regression.

Method

Because of the computing time needed for estimating each point in the distributions by Monte Carlo simulation (between 10 sec and 5 min.), a four-stage procedure was used: (a) initial approximation of values in order to select suitable nodes for Monte Carlo estimation, (b) Monte Carlo simulation of the selected nodes, (c) smoothing of the Monte Carlo estimates by graphical and least squares methods, and (d) testing fitted values by new Monte Carlo simulation. Since most of the tabled values were not initially estimated by Monte Carlo, a check on the smoothing process itself was possible in the last stage.

Approximation

The iterative function (Equation 3) was used to generate values of $R^2(k, m, n, \alpha)$ for $k = 1$–m; $m = 2$–30; $n - m - 1 = 10, 20, 30, 40, 50, 60, 70, 80, 90, 100, 150$, and 200; and $\alpha = .05$ and .01. From these values, suitable nodes were selected for fitting nomographs in the two tables to be constructed. These nodes were the known values at $k = 1$ and $k = m$ for $n - m - 1 = 10, 20, 50, 100$, and 200, plus the subsets $(k, m) = (2, 3), (3, 4), (2, 7), (4, 7), (3, 12), (7, 12), (3, 20), (7, 20)$, and $(12, 20)$ at the same degrees of freedom.

Note. Decimals are omitted; m = number of predictors; k = number of predictors selected; n = sample size.

Data Generation

Two FORTRAN subroutines were written for the Monte Carlo simulation. The first generated a sample correlation matrix directly from a standardized Wishart distribution given m and n and using an algorithm from Odell and Feiveson (1966). The second subroutine used the abbreviated Gauss-Doolittle method with forward selection to compute a sample R^2 value (Draper & Smith, 1966, p. 178). Sample R^2 values were sorted and noted at the 95th and 99th percentage points after 500 replications. Additional replications in blocks of 100 were continued in each run until a stopping rule was satisfied. The stopping rule was that the upper 99th percentile value be bound on either side by a value differing from it by lesss than .01. Computations were done in double precision on an IBM 370/158 using the FORTRAN H extended compiler and the sort (KB01AD) and normal random number (FA03A) routines from the *Harwell Subroutine Library* (1973).

Note. Decimals are omitted; m = number of predictors; k = number of predictors selected; n = sample size.

Curve Fitting

The nodes from the Monte Carlo simulation and the known values at $k = 1$ and $k = m$ were used to draw nomographs for $n - m - 1 = 10$–200, $m =$ 2–20, and $k = 1$–m. Initial estimates of the entries in Tables 1 and 2 were read off these nomographs. Most of these values were not estimated directly by Monte Carlo.

To smooth further the results from the nomographs, the 656 entries in each table (including the known values) were predicted by multiple regression. Twenty linear and nonlinear terms plus their interactions were constructed from approximations contained in Diehr and Hoflin (1974), Zirphile (1975), and Kendall and Stuart (1969, p. 330). The standard error of the estimate in predicting the 95th percentile table values from the best 15 terms in

the equation was .0054; for the 99th percentile table, it was .0047. The entries in Tables 1 and 2 were taken from the regression estimates.

Check on Accuracy

As a check on the accuracy of the table values, simulations were run to predict 20 points that had not previously been estimated by Monte Carlo. Runs were continued in blocks of 1,000 replications until a stopping rule was met. The stopping rule was that two cumulative runs result in a successive difference of less than .01 in both the 95th and 99th percentile values. Of the 40 values tested in the combined tables, 17 differed from the Monte Carlo value by .01, and 23 agreed exactly with the printed accuracy. No significant differences in errors were found across tables.

Results

Histograms of the simulated data at selected parameter values resembled beta distributions, although no beta-type function could be found to reproduce accurately the upper tail values. Tables 1 and 2 give the 95th and 99th percentage points of these distributions.

Use of Tables

The tables have been constructed to cover a full range of practical parameter values. Linear interpolation works quite well for m and n. For interpolations on k, however, graphical plotting of the table values provides more accurate estimates. Extrapolation may be used moderately, since the values near the margins of the table change slowly. The known values when m and n are large, for example, can be extrapolated accurately on fine graph paper with a flexible drafting curve.

Discussion

The tables clearly illustrate the inflation of the sample R^2 in stepwise regression that has frequently been noted by statisticians. For example, $R^2(4, 4, 35, .05) = .26$, whereas $R^2(4, 20, 35, .05) = .51$. This inflation has not always been noted by researchers, however. A computer-assisted search for articles in psychology using stepwise regression from 1969 to 1977 located 71 articles. Out of these articles, 66 forward selection analyses reported as significant by the usual F tests were found. Of these 66 analyses, 19 were not significant by Table 1.

The extent of this artifact may have contributed to the poor reputation of subset selection methods in multiple regression through failures to replicate published research. This situation is ironic because of the clear evidence of the substantial superiority of forward selection over ordinary least squares in a variety of prior distributions. Forward selection can be almost as effective as ridge regression in minimizing prediction and beta weight errors with highly correlated predictors (Dempster et. al., 1977). Furthermore, forward selection offers a more parsimonious model than does ridge regression because only k predictors out of m are included in the equation.

Three questions remain, however, regarding the application of these tables: (a) Can the tables be used for other subset selection methods? (b) Can they be used when predictors are intercorrelated? (c) Do they apply when k is not known prior to the analysis?

In answer to the first question, the tabled values may be compared to results from Monte Carlo studies of two other subset selection methods: best subset (Diehr & Hoflin, 1974) and stepwise selection and elimination (Rencher & Fu-Ceayong, Note 2). Diehr and Hoflin's approximation, given in Equation 3, yields values higher than those in Tables 1 and 2. The differences range from .01 when $m = 3$ to .10 when $m = 20$. This discrepancy is due partly to the approximation and partly to the fact that the sample R^2 percentage point for the best subset case is an upper bound for all subset R^2 percentage points at the same parameter values. Rencher and Fu-Ceayong's results fit the values within both tables closely. For 15 comparable parameter values in both tables, the largest discrepancy was .02, with most values less than .01. This fit indicates that the tables should be appropriate for stepwise selection and elimination. Although the various other suboptimal selection methods used

in most computer programs occasionally result in different subsets of size k from $\binom{m}{k}$, the distribution of the sample R^2 in these cases may nevertheless fit these tables, particularly when m is large and k is small.

The question of intercorrelated predictors requires further Monte Carlo simulation for an answer. Rencher and Fu-Ceayong investigated this problem using stepwise regression on random predictors intercorrelated in various ways. The upper percentage points of the sample R^2 distributions from correlated predictors were only slightly lower than those for independent predictors in all cases. The results for forward selection should be similar. In any case, loss of power should not be substantial when these tables are used for correlated predictors, provided k is small relative to m.

Finally, when k is unknown prior to the analysis, stopping rules must be applied (Bendel & Afifi, 1977). In this case, k is a random variable instead of a fixed constant. Further Monte Carlo research is needed to identify the effect of stopping rules on the sample R^2 distribution. The most common stopping rule for forward selection is to continue stepping until the sample partial correlation is "nonsignificant" by a standard F test (Draper & Smith, 1966, p. 71). As an alternative, simultaneous inference may be used for subset selection to control the Type I family error rate (Aitkin, 1974). This method is conservative, however, like most simultaneous test procedures; for a given critical level, it will eliminate fewer subsets containing "unimportant" predictors than will forward selection with a sequential stopping rule.

Problems remain regarding tests of significance of coefficients in stepwise regression. In lieu of such tests, cross-validation should be performed, even though the standard errors of the coefficients may be smaller than those in the corresponding ordinary least squares equation on m variables. Researchers should carefully consider the advantages and disadvantages of various subset selection methods and other biased estimation methods for analyzing particular data sets (for reviews, see Hocking, 1976, and Jennrich, 1977). Users of standard, automated stepwise computer programs, however, should choose forward selection, ignore the tests of significance printed at each step, and consult Tables 1 and 2 to evaluate the significance of the final equation they select.

Suppression of Responding During Signaled and Unsignaled Shock

Norman Hymowitz
New Jersey Medical School
College of Medicine and Dentistry of New Jersey

The empirical basis for Seligman's safety signal hypothesis derives largely from studies of response suppression during signaled and unsignaled shock and from studies of animals' preference for signaled over unsignaled shock. Recently, the literature on preference for signaled over unsignaled shock has been the subject of serious criticism and controversy, thus weakening the empirical foundations of the safety signal hypothesis. The present article reviews the literature on response suppression to determine if this, too, has been the subject of controversy and criticism. To the contrary, the suppression literature provides strong support for the safety signal hypothesis and also reports data that are compatible with much of the choice literature. This agreement between the two tests of the safety signal hypothesis increases confidence in the reliability of the data and the adequacy of the hypothesis. Despite this agreement, emerging data on response suppression during signaled and unsignaled shock suggest that, at best, the safety signal hypothesis emphasizes only one of the many determinants of differential response suppression.

Seligman (1968) reported that food-maintained responding was more readily suppressed by a given intensity of electric shock when shock delivery was unsignaled than when it was signaled. Furthermore, animals exposed to unsignaled electric-shock delivery developed significantly more gastric ulcers than did animals exposed to comparable signaled shock. Seligman interpreted these findings in terms of a safety signal hypothesis. According to this hypothesis, the presence and absence of the preshock signal or conditioned stimulus (CS) specify shock ("danger") and shock-free ("safety") occasions, respectively. During signaled shock, the animals spend most of the session in safety. With unsignaled shock, most of the session is spent in danger. Presumably, this differential exposure to danger and safety is responsible for differential response suppression and ulceration during signaled and unsignaled shock.

Since Seligman's report the analysis of the behavioral effects of signaled and unsignaled electric-shock delivery has proceeded in two directions. On the one hand, a host of researchers have attempted to systematically replicate Seligman's (1968) original findings with response suppression as the data of interest. As noted by Seligman and Binik (1977), such studies have uniformly confirmed Seligman's finding of more response suppression during unsignaled than during signaled shock. A second avenue of investigation involved choice of signaled over unsignaled shock delivery as the dependent measure. According to the safety signal hypothesis, animals ought to select signaled over unsignaled electric-shock delivery. Indeed, a host of investigators have suggested that this is the case (e.g., Badia & Culbertson, 1972; Badia, Culbertson, & Harsh, 1973; Harsh & Badia, 1975; Lockard, 1963; Perkins, Seymann, Levis, & Spencer, 1966). However, some negative findings (e.g., Biederman & Furedy, 1973, 1976b; Crabtree & Kruger,

Requests for reprints should be sent to Norman Hymowitz, Behavioral Sciences Unit, Department of Psychiatry and Mental Health Sciences, New Jersey Medical School, 100 Bergen Street, Newark, New Jersey 07103.

1975) and serious methodological criticisms of the choice literature (e.g., Biederman & Furedy, 1976a; Furedy, 1975) exist.

As noted by Biederman and Furedy (1976a), many of the earlier studies of animals' preference for signaled over unsignaled shock used unscrambled grid shock (e.g., Lockard, 1963). Since animals may modify or avoid unscrambled shock by postural adjustment, unambiguous evaluation of such studies is not possible. Moreover, Biederman and Furedy (1973) found preference for signaled over unsignaled shock when the shock was unscrambled but not when it was scrambled.

Two studies reported preference for signaled shock over unsignaled shock when shock was delivered to the animals through electrodes attached directly to the animal's tail (Miller, Daniel, & Berk, 1974; Perkins et al., 1966). Since it is not possible to modify shock delivered through tail electrodes, the data seem to support the safety signal hypothesis. However, Biederman and Furedy (1976a, 1976b) pointed out that the tail electrode procedure was unreliable and that many of the animals were eliminated from the studies because of damage to the electrodes. In view of the unreliable procedure and possible sampling bias, the data may hardly be viewed as strong support for the safety signal hypothesis.

A more recent study by Miller, Marlin, and Berk (1977) that employed tail shock is less susceptible to serious criticism. Miller and his students perfected their apparatus and technique so that they were able to successfully and reliably deliver shock directly to the tail of freely moving animals (Berk, Marlin, & Miller, 1977). Five of the eight animals studied showed consistent preferences for the side of the shuttle box associated with signaled shock. The three other animals revealed an initial preference for signaled shock, but failed to maintain the preference during the course of several reversal conditions in which the side of the shuttle box associated with signaled shock was changed.

Perhaps the most thorough analyses of animals' preference for signaled over unsignaled shock are those that were conducted by Badia and his students (Badia & Culbertson, 1972; Badia et al., 1973; Harsh & Badia, 1975). Badia used a changeover procedure to study the choice behavior of rats. Typically, the animals were exposed to unsignaled electric-shock delivery. Responses on the changeover lever produced, for a brief period of time, a correlated stimulus in the presence of which shocks were preceded by a signal. He also used scrambled grid shock. Hence, his studies are not subject to the criticisms mentioned earlier. However, Biederman and Furedy (1976a, 1976b) criticized Badia's studies on several other counts. According to Biederman and Furedy, Badia typically confounded the correlated stimulus and the CS; that is, the same response that produced the correlated stimulus (light) also produced the preshock signal or CS (tone). Biederman and Furedy (1973) showed that during shock animals pressed to produce a light (correlated stimulus) whether or not shock was preceded by the CS. They suggested that changeover responding was maintained by stimulus change or photic reinforcement, not by signaled shock per se. Biederman and Furedy (1976a, 1976b) also noted that Badia's studies were not balanced. Animals changed over from dark, unsignaled shock to light, signaled shock. If given the opportunity, they might have changed over from light, signaled shock to dark, unsignaled shock.

It is not the purpose of the present article to evaluate the pros and cons of the various discrepancies and controversies in the choice literature (see Badia & Harsh, 1977a, 1977b). Polemics are no substitute for carefully planned experiments. However, closer attention to the first avenue of investigation mentioned above, the suppression of responding during signaled and unsignaled shock, may advance the analysis of the behavioral effects of signaled and unsignaled shock and also may bear upon some of the discrepancies in the choice literature. When, for example, a variable is shown to influence choice of signaled over unsignaled shock and differential response suppression during signaled and unsignaled shock in the same manner, more con-

fidence can be placed in the generality and reliability of the data and in the hypothesis under test (Ghiselin, 1969). Thus, one purpose of the present review of the literature on response suppression during signaled and unsignaled shock is to determine, wherever possible, whether variables purported to influence the choice of signaled shock also influence differential response suppression. Such an analysis should enhance our understanding of the behavioral effects of signaled and unsignaled shock and should suggest additional studies that bear critically on existing controversies in the choice literature.

A second purpose of the present review is to evaluate further the utility of the safety signal hypothesis. It is important to note that the safety signal hypothesis originally was formulated on the basis of findings on differential response suppression (Seligman, 1968). Can the hypothesis accommodate the data that have been generated since 1968? How general are Seligman's (1968) original findings? The following review of the literature provides answers to these questions.

Naturally, all reviews of the literature must be selective. I did not include in the review the growing literature on the somatic effects of signaled and unsignaled shock. For the most part, the focus of research in this area has been upon producing somatic reactions with little attention given to the animal's behavior. Where appropriate, studies from related areas of aversive conditioning are cited and discussed. In particular, studies of choice of signaled over unsignaled shock are presented in detail. To facilitate the comparison of variables that influence choice and suppression in the same manner, the ensuing literature review is organized according to the variables of which differential response suppression is a function.

Experimental Design

Two basic experimental designs have been employed to study differential suppression. With between-groups designs (e.g., Seligman, 1968), the data of interest are comparisons between the rate of responding in the absence of the CS for one group of animals and the rate of responding during comparable unsignaled shock delivery for another group. For within-subject designs (e.g., MacDonald, 1973) the rate of responding in the same animal is studied under signaled as well as unsignaled shock conditions (cf. Sidman, 1960).

MacDonald (1973; MacDonald & Baron, 1973) studied rates of responding in the rat under a two-component multiple schedule in which each component consisted of a two-link chained schedule. Under this schedule, responding in one of the initial links of the chain schedules produced one of the two terminal links during which food reinforcers and either signaled or unsignaled shocks were presented. When signaled and unsignaled electric-shock delivery was scheduled in the separate terminal links, the rats responded at lower rates in the initial and terminal links associated with unsignaled shock. Hymowitz (1976b, 1977b) studied responding within the same animal during multiple and mixed schedules of signaled and unsignaled electric-shock delivery. Much more response suppression occurred in the components of the multiple schedule that were associated with unsignaled shock than in the components associated with comparable signaled shock. Differential response suppression during signaled and unsignaled shock delivery was not obtained when the animals were exposed to the mixed schedule of shock delivery. The significance of the latter finding is discussed in another section.

Although the between-groups and within-subject designs yield compatible results, the within-subject design seems more suitable for parametric analyses. Each animal may differ with respect to the conditions necessary to reveal differential suppression (cf. Hymowitz, 1977b). Factorial designs provide information about parameter values, but do not overcome the differences in sensitivity of individual animals to experimental conditions. A case in point is the present controversy in the literature on the preference for signaled over unsignaled shock.

Several researchers (Biederman & Furedy, 1973, 1976a, 1976b; Crabtree & Kruger, 1975; Furedy & Biederman, 1976) failed to find preferences in animals for signaled over

unsignaled electric-shock delivery. Other investigators (e.g., Badia & Culbertson, 1972; Harsh & Badia, 1976) routinely report positive results. One difference among these researchers is their selection of experimental designs. The former have typically employed between-subjects designs, whereas the latter have studied the behavior of individual animals under a wide range of parameter values. At some parameter values, animals selected signaled shock; at others, they did not. Often, parameters such as shock intensity required adjustment and manipulation during the course of the study to successfully demonstrate preference. Although each of the researchers presented data that bear on our understanding of the preference-of-signaled-shock phenomenon, one wonders whether the difference in the nature of their findings is not in part because of their selection of experimental designs. Within-subject designs are, by definition, better suited for the analysis of phenomena that require constant adjustment of parameter values for individual animals.

Recent studies (Hymowitz, 1977a, 1977b) showed that parametric considerations are of paramount importance in the analysis of differential suppression during signaled and unsignaled shock. These studies are discussed in more detail in later sections, but briefly their results showed (a) that animals differ with respect to shock intensities that yield differential suppression and (b) that for the same animal, a given shock intensity may yield differential suppression of one response but not of another. The failure to adequately take into account individual differences in sensitivity to important controlling parameters may lead to seriously misleading conclusions.

Duration of the CS

Does the duration of the CS in any way affect the differential suppression of responding during signaled and unsignaled shock? No study systematically attempted to answer this question. It is known that CS durations of 60 sec (e.g., Seligman, 1968), 10 sec (Hymowitz, 1977a), and 5 sec (e.g., Hymowitz, 1976b) readily yield differential suppression during signaled and unsignaled shock. In preference situations, it does not seem to matter whether CSs of 3, 5, 10, 20, or 30 sec are employed. Animals readily select the signaled over the unsignaled shock condition (French, Palestino, & Leeb, 1972).

Very likely, the effects of the CS duration on differential response suppression and on preference for signaled over unsignaled shock depend on the relative duration of the CS compared to non-CS occasions. Such a finding would not be inconsistent with Seligman's (1968) safety signal hypothesis. In studies of conditioned suppression (Stein, Sidman, & Brady, 1958), the suppression of responding during the CS depended on the relative durations of CS and non-CS occasions. In brief, when the CS duration was short, relative to between-stimuli durations, responding tended to be more suppressed during the CS than on occasions when the duration of the CS was relatively long. Indeed, Harsh and Badia (1976) employed a CS duration of 30 sec and showed that rats failed to prefer signaled over unsignaled shock when the shock was delivered on the average of once every 45 sec. Preference was observed within the same animals when shock was delivered less frequently. Perhaps the 45-sec shock delivery schedule would have yielded preference for signaled shock if a shorter CS had been employed.

Perkins et al. (1966), on the other hand, failed to find preference for signaled over unsignaled shock when the CS was only .5 sec, although shock was delivered on the average of once every 5 min. They did report preferences for signaled shock with CS durations of 3 and 18 sec. These findings are compatible with Perkins' (1968) preparedness hypothesis. According to this hypothesis, one important reason why animals select signaled over unsignaled shock (or suppress responding more during unsignaled than during signaled shock) is that the CS enables animals to prepare for the impending shock. Presumably, .5 sec is not enough time for such preparation. It would be highly informative to determine if differential response suppression during signaled and unsignaled shock occurs with a brief .5-sec duration CS. An

answer to this question would bear critically on the preparedness hypothesis.

Shock Parameters: Intensity, Duration, and Frequency

Shock Intensity

There is little doubt that the suppression of food-maintained responding generally is directly related to shock intensity. The higher the intensity, the greater is the suppression (cf. Azrin & Holz, 1966; Church, 1969; D'Amato, 1970). Similarly, the suppression of responding in the presence of the CS in the conditioned suppression paradigm also is a function of shock intensity (cf. Kamin, 1965).

Seligman and Meyer (1970) studied the effects of shock intensity on responding during signaled and unsignaled shock. Using a between-groups design and two shock intensities, .60 and 1.00 mA, they showed (a) that for both shock intensities, more response suppression occurred in the groups of rats exposed to unsignaled shock; (b) that responding during unsignaled, mild (.60 mA) shock recovered considerably over sessions; and (c) that little if any recovery during unsignaled 1.0 mA shock occurred.

Hymowitz (1977b) extended these findings. He conducted a within-subject analysis of shock intensity in which each animal was systematically subjected to a wide range of shock intensities. Lever pressing was studied first during 20–25 sessions of multiple fixed-ratio 10 fixed-ratio 10 (multiple FR 10 FR 10) (Rat 1) and multiple FR 20 FR 20 (Rats 2 and 3) food delivery schedules. A multiple variable-time 120-sec variable-time 120-sec (multiple VT 120-sec VT 120-sec) schedule of shock delivery was then superimposed upon the food schedule. In one component of the multiple schedule, a 5-sec tone preceded each shock (signaled shock). In the other component, the preshock stimulus was not presented (unsignaled shock). Blocks of 5–10 successive food-and-shock sessions at a constant shock intensity alternated with blocks of 3–5 successive food-alone sessions. Each component was 6 min. in duration, and each daily session terminated after eight components.

The major findings of this study may be summarized as follows: (a) Each animal differed with respect to the intensities of shock that led to differential response suppression; (b) relatively mild intensities of shock had little effect on responding in the components of the multiple schedule associated with signaled and unsignaled shock, intermediate intensities disrupted responding primarily in the component associated with unsignaled shock, and more severe intensities disrupted responding in both components; and (c) continued testing under signaled and unsignaled shock delivery affected the minimum intensity of shock required to produce differential suppression. Originally, .30 mA shock failed to yield differential response suppression in two of the animals. Following additional testing under higher intensities of shock, signaled and unsignaled shock intensities of .20 mA and .30 mA readily led to more response suppression during unsignaled than during signaled shock in each of the animals.

It should be noted that Hymowitz's (1977b) suppression data are in fairly close agreement with choice data reported by Harsh and Badia (1976). In Badia's (e.g., Badia & Culbertson, 1972; Harsh & Badia, 1976) studies, the animals were exposed to unsignaled response-independent electric-shock delivery. Responses on a changeover lever produced for a brief period of time a correlated stimulus in the presence of which a brief tone preceded shock delivery. Harsh and Badia (1975) reported that changeover responding from unsignaled to signaled shock was a function of shock intensity. At intensities of shock of less than .60 mA, little changeover responding occurred initially. As the intensity increased, the animals spent more time in the changeover condition. Moreover, when the intensity was reduced to .40 mA, changeover responses still occurred at a high rate.

Duration of Shock

Like shock intensity, the duration of shock is directly related to the suppression of re-

sponding. For a given shock intensity, the longer the duration, the greater is the response suppression (e.g., Church, Raymond, & Beauchamp, 1967). Only MacDonald (1973) and MacDonald and Baron (1973) employed shock durations of longer than .50 sec. They used a duration of 2.00 sec and found more suppression in the links of a multiple chain schedule associated with unsignaled shock than in the links associated with signaled shock. It is unfortunate that more systematic data on the effects of shock duration on differential suppression are not available. Studies of choice of signaled over unsignaled shock (Badia et al., 1973) suggest that changeover from unsignaled to signaled shock is a function of shock duration. At durations of signaled shock beyond 2.00 sec, animals ceased changeover responding from briefer unsignaled shock.

It is interesting to note that studies that failed to find preferences for signaled over unsignaled scrambled shock delivery used shock durations of 5.00 sec (Biederman & Furedy, 1973, 1976b; Furedy & Biederman, 1976) and 2.00 sec (Crabtree & Kruger, 1975). Studies that showed preference for signaled and unsignaled scrambled shock delivery (e.g., Badia & Culbertson, 1972; Hymowitz, 1973c) used brief .50-sec shock durations. Parametric studies of the effects of shock duration on response suppression during signaled and unsignaled shock delivery may better describe the relationship between shock duration and responding during signaled and unsignaled shock.

Shock Frequency

The frequency of shock delivery, like the duration and intensity of shock, generally is directly related to response suppression. The more frequent the shock, the greater is the suppression of responding (cf. Azrin & Holz, 1966). The frequencies of shock delivery under which differential response suppression during signaled and unsignaled shock delivery has been found range from an average of one shock every 11 min. (Davis, Memmott, & Hurwitz, 1976) to one every 4 min. (MacDonald & Baron, 1973), 2 min. (Hymowitz, 1976a), 1 min. (Hymowitz, 1973a), and 45 sec (Imada & Okamura, 1975). Although shock frequency undoubtedly influences differential suppression, it is clear that differential response suppression occurs under a wide range of shock frequencies.

It is of some interest that preference for signaled over unsignaled shock is affected by the frequency of shock delivery. If shock delivery is too frequent (i.e., once every 45 sec), little if any preference for signaled shock is found (Harsh & Badia, 1976). In terms of Seligman's (1968) safety signal hypothesis, the failure to obtain preference at relatively short intershock intervals suggests that some minimum period of shock-free time is required to maintain changeover responses.

Again, an analysis of the effects of relatively dense and lean schedules of shock delivery on differential response suppression would be informative. Such an analysis might accompany an analysis of shock intensity; that is, for each shock frequency, one would determine the range of shock intensities that (a) mildly affects responding during signaled and unsignaled shock, (b) suppresses responding primarily during unsignaled shock, and (c) severely suppresses responding under signaled as well as unsignaled shock. Very likely, the shock intensities required to produce these effects would vary as a function of shock frequency. It is an empirical question, however, whether some minimum period of safety is necessary to produce differential response suppression during signaled and unsignaled shock.

Response-Independent and Response-Dependent Electric-Shock Delivery

Most of the studies of the suppressive effects of signaled and unsignaled shock employed response-independent shock delivery. Two studies (Hymowitz, 1976b; MacDonald, 1973) used response-dependent shock delivery schedules. Although it is not possible to discuss the relative contribution of the contingency between shock and responding to differential response suppression on the basis of the available literature, it is clear that each mode of shock presentation is conducive to differential suppression.

It is surprising that more data on this variable are not available. Although there is some question as to whether responding is suppressed more by response-dependent than by response-independent shock delivery (e.g., Azrin, 1956; Camp, Raymond, & Church, 1967; Church, 1969; Church, Wooten, & Matthews, 1970; Hoffman & Fleshler, 1965; Orme-Johnson & Yarczower, 1974; Rachlin & Herrnstein, 1969), it is generally accepted that responding in the absence of the CS in conditioned suppression studies is more affected by response-independent than by response-dependent shock that is delivered in the presence of the CS (Hoffman & Fleshler, 1965; Hunt & Brady, 1955; Orme-Johnson & Yarczower, 1974). Such differences between the two modes of shock delivery might be expected to influence the differential suppression of responding during signaled and unsignaled shock.

Schedule of Electric-Shock Delivery

Only one study (Hymowitz, 1973a) compared the rate of responding during signaled and unsignaled shock delivery during different schedules of shock presentation. For both fixed-interval and variable-interval shock delivery schedules, more suppression of baseline responding was found for animals exposed to unsignaled than to signaled shock. There was little if any difference in suppression between the signaled fixed- and variable-interval conditions.

When the percentage of occasions on which the CS preceded shock was decreased from 100% to 50%, the importance of the schedule of shock delivery was apparent. Much more suppression of baseline responding was found in the 50% variable-interval than in the 50% fixed-interval condition. For the variable-interval shock schedules, as much or more suppression occurred in the 50% as in the unsignaled shock condition (0%). For the fixed-interval shock delivery schedule, the most suppression occurred during unsignaled shock, the least during 100% signaled shock, and an intermediate amount during 50% signaled shock. These findings are discussed further in the section entitled Predictability of Shock. Considering the importance of the schedule of shock delivery for the suppression of responding in other situations (e.g., Azrin, 1956; Camp, Raymond, & Church, 1966; Ferraro, 1967; Morse & Kelleher, 1966), it is not surprising that the schedule interacts with the predictability of shock to influence the course and degree of response suppression.

Appetitive Factors: Food Schedule and Food Deprivation

Schedule of Food Delivery

The schedule and frequency of food delivery influence the manner in which responding is suppressed by noxious events (e.g., Azrin & Holz, 1966). Relatively little is known about their influence on differential response suppression during signaled and unsignaled shock, although it is expected that the frequency and schedule of food delivery will interact with the shock delivery conditions.

In terms of the generality of the effects of signaled and unsignaled shock delivery, it is noteworthy that Hymowitz found differential suppression when food pellets were delivered under variable-interval (Hymowitz, 1976b), fixed-ratio (Hymowitz, 1977b), and fixed-interval (Hymowitz, 1977a) schedules. Imada and Okamura (1975) studied the effects of signaled and unsignaled shock delivery on operant licking in water-deprived animals. Licking was reinforced on a continuous reinforcement schedule. More suppression of licking was found during unsignaled than during signaled shock conditions. These data certainly enhance the generality of Seligman's (1968) original findings obtained with variable-interval food delivery schedules.

Although direct comparisons among the different food schedules used in the abovementioned studies are not possible, it is noteworthy that the manner in which responding is affected by signaled and unsignaled shock is influenced by the schedule of food delivery. With fixed-ratio food delivery, for example, shock led to increases in the length of the postpellet pause, but had little effect on the running rate until much more intense shocks were delivered (Hymowitz, 1977b). For a

given shock intensity, the pausing was much more apparent in the component of the multiple schedule associated with unsignaled shock. At some intensities, little if any pausing occurred during signaled shock, whereas marked pausing occurred during unsignaled shock.

Food Deprivation

As noted by Millenson and de Villiers (1972), the contribution of food deprivation to response suppression, though very important, is a relatively neglected area of research. This is somewhat surprising because food deprivation plays an important role in motivational analyses of punishment (Estes, 1969) and conditioned suppression (Millenson & de Villiers, 1972). Moreover, there is little doubt that this variable interacts with the schedule and frequency of food delivery to determine the resistance of responding to the suppressive effects of electric-shock delivery. Future analyses of response suppression during signaled and unsignaled shock ought to include this variable in the design of the experiment. At present, virtually no data on the effects of food deprivation on differential suppression during signaled and unsignaled shock have been published, although the suppression of responding in the presence of the CS is influenced by food deprivation (Millenson & de Villiers, 1972).

Dependent Variable

Myers (1971) noted that too much of our knowledge about response suppression derives from studies in which operant lever pressing served as the dependent variable. He questioned the generality of the lever-press findings to other response systems. Studies of autoshaping, learned taste aversions, species-specific defense reactions, and schedule-induced behaviors (cf. Bolles, 1972; Seligman, 1970) produced data that seriously question the generality of principles of learning derived primarily from analyses of key pecking in pigeons and lever pressing in rats. One may similarly question the generality of the data on signaled and unsignaled shock, since most investigators employed schedule-controlled lever pressing as the dependent variable. Some data recently collected with schedule-induced water intake as the dependent variable serve to extend the generality of the lever-press findings (Hymowitz, 1977a).

Schedule-induced water intake was first reported by Falk (1961) and refers to post-pellet water intake that occurs when food-deprived rats, mice, pigeons, or monkeys are exposed to any one of a number of intermittent schedules of food delivery (Falk, 1971; Segal, 1972; Staddon, 1975, 1977a, 1977b). Induced water intake may be distinguished from normal regulatory drinking. With schedule-induced drinking, the animals are not water deprived, and the amount of water consumed may be far in excess of physiological requirements (polydipsia). Induced drinking may also be distinguished from paradigms in which licking serves as an operant on which the delivery of food is dependent. Schedule-induced licking follows pellet delivery and persists even though licking may postpone the delivery of the food pellet (Falk, 1971).

An adequate explanation of schedule-induced water intake must take into account that drinking is but one of a number of responses that animals may engage in following pellet ingestion. Other schedule-induced behaviors are schedule-induced wheel running, pica, escape, air licking, and attack (Falk, 1971). A common feature of each behavior is that they occur during those occasions when the probability of food delivery is low. Thus, they may be related to aversive aspects of intermittent positive-reinforcement schedules. Falk (1971) also noted that the induced behaviors seem not to be related to the task at hand—the procurement of food pellets. He termed these behaviors *adjunctive* behaviors and likened them to displacement activities more commonly studied by ethologists. Staddon (1975, 1977a, 1977b) distinguished between *interim* behaviors, such as schedule-induced water intake and grooming, which occur during occasions when food pellets are not available, and *terminal* behaviors, such as lever pressing, which occur when food pellets are available. Interactions between the two behaviors may provide the

underlying structure for schedule performances observed in the operant chamber.

Although the exact nature of schedule-induced water intake eludes researchers at present, schedule-induced water intake may serve as a useful dependent variable for the analysis of the behavioral effects of signaled and unsignaled electric-shock delivery. Schedule-induced licking shares with schedule-controlled lever pressing many features of a desirable dependent variable. It is a highly quantifiable sample of behavior that remains quite stable from session to session. Moreover, it also is sensitive to variables such as the frequency of food delivery (Falk, 1967; Freed & Hymowitz, 1972), the magnitude of the food pellet (Falk, 1967; Freed & Hymowitz, 1972), body-weight loss (Freed & Hymowitz, 1972), shifts in the rate of reinforcement (Jacquet, 1972), and the delivery of electric shock (e.g., Hymowitz & Freed, 1974). Comparisons of the effects that various conditions of signaled and unsignaled shock have upon the suppression of schedule-controlled and schedule-induced behavior may provide useful insight into the role that the nature of the response has in the suppression of behavior in general.

Recent studies (Bond, Blackman, & Scruton, 1973; Dunham, 1971; Freed, Hymowitz, & Fazzaro, 1974; Hymowitz, 1973b, 1976a; Hymowitz & Freed, 1974) showed that schedule-induced licking was suppressed by shock in very much the same manner as lever pressing. However, the intensity of shock required to suppress induced licking was lower than the intensity required to suppress lever pressing (Bond et al., 1973; Hymowitz & Freed, 1974). Subsequent studies (Hymowitz, 1976a) showed that the greater sensitivity of induced licking to shock was not simply due to the possibility that shock was more often delivered while the animals were licking than while they were pressing. Schedule-induced licking was similarly suppressed by shock that was separated in time from licking by 1, 5, 10, and 15 sec (Hymowitz, 1976a).

In a recent study, Hymowitz (1977a) employed schedule-induced licking, as well as schedule-controlled lever pressing, as a dependent variable. Food was delivered under a fixed-interval 40-sec schedule. Following the acquisition of stable levels of schedule-induced and schedule-controlled behavior, the animals were exposed on separate occasions to signaled and unsignaled electric-shock delivery. Electric shock was delivered according to a variable-time 70-sec schedule. During signaled shock, a 10-sec signal light preceded each shock. Blocks of successive food-and-shock sessions at a constant shock intensity alternated with blocks of successive food-alone sessions.

The data produced by this study were consistent with the author's previous findings (Hymowitz, 1977b). For both lever pressing and schedule-induced licking, differential response suppression during signaled and unsignaled shock was a function of shock intensity. At some intensities, pressing and licking either were unaffected during signaled and unsignaled shock, suppressed primarily during unsignaled shock, or equally suppressed during signaled and unsignaled shock. Moreover, the intensity of shock required to suppress licking generally was lower than for lever pressing. Hence, licking often ceased during signaled shock delivery, whereas lever pressing was maintained at a high rate. The finding that one behavior occurs at a high rate during signaled shock whereas another is totally suppressed has considerable theoretical importance. It is not clear how such a finding can be explained by Perkins' (1968) preparedness hypothesis or Seligman's (1968) safety signal hypothesis. If the animal is prepared sufficiently to continue pressing or if it is safe to press, why is the animal not prepared sufficiently to continue licking, and why is it not safe to lick?

Differential response suppression during signaled and unsignaled shock also has been reported with operant licking (e.g., Imada & Okamura, 1975). As noted previously, it is important to distinguish between operant and induced licking. In the former, the animals are water deprived and given limited access to water in the test situation. For schedule-induced licking, the animals are not water deprived, and licking occurs as an adjunct (cf. Falk, 1971; Segal, 1972) to ongoing food-

maintained responding. Typically, animals lick after the ingestion of each food pellet (e.g., Falk, 1961). Clearly, Seligman's (1968) original findings pass the test of response generality (cf. Sidman, 1960). However, the available data suggest the response studied may be an important determinant of suppression during signaled and unsignaled shock. Further studies of operant and adjunctive behaviors appear warranted. In particular, it is of considerable interest to determine why schedule-induced licking is suppressed during signaled shock conditions in which schedule-controlled lever pressing is maintained at a high rate. The greater sensitivity of induced licking to shock may simply be due to the nature of the response (lever pressing versus licking), to the relative strength of schedule-induced and controlled behavior per se, or to the rate at which each behavior occurs. With respect to the latter possibility, Blackman (1977) noted that behaviors that occur at a high rate are more affected by a given intensity of shock than are behaviors that occur at a low rate. He referred to this as a *rate-dependency effect*. Since licking generally occurs at a higher rate than does lever pressing, this hypothesis certainly warrants further attention. It is noteworthy, however, that McKearney (1973) showed that the rate of licking was not a factor in determining the effects on induced licking of the drug methamphetamine. With schedule-controlled licking, rate was a major determinant of the drug's effect (rate-dependency effect).

Predictability of Shock

Rescorla (1968) showed that CSs acquired their suppressive or aversive properties only when they reliably specified the advent of shock delivery. When shock occurred with the same probability in the absence and in the presence of the to-be-conditioned stimulus, little conditioning occurred. To what extent is differential response suppression during signaled and unsignaled shock a function of the probability that a CS precedes each shock in the signaled shock condition? Hymowitz (1973a, Experiment 3) employed a 2 × 3 experimental design with sessions as repeated measures. The factors were the schedule of shock delivery (fixed interval or variable interval) and the percentage of occasions on which a 5-sec CS preceded shock delivery —100%, 50%, or 0%.

For the 100% signal condition, the presence and absence of the signal reliably indicated shock and shock-free occasions. For both schedules of shock delivery, the least amount of response suppression occurred in this condition. Responding virtually ceased during the CS, but was maintained at a high rate in its absence. For the 0% signal condition, the presence and absence of shock were not specified. Although the fixed-interval schedule may have provided temporal cues, there was little if any difference in response suppression for the groups of rats exposed to either shock schedule. Both groups revealed marked response suppression with little recovery during the 10 test sessions.

Perhaps the most interesting groups were those for which the CS preceded shock on 50% of the shock occasions. The presence of the CS reliably indicated shock occasions, but the absence of the CS did not reliably indicate shock-free occasions. For variable-interval shock delivery, as much suppression occurred under this condition as under the 0% condition. For fixed-interval shock delivery, in which temporal factors may have specified to some degree the presence and absence of shock, an intermediate degree of response suppression occurred. There was more response suppression than in the 100% condition, but much less than in the 0% condition.

Comparable findings were obtained in preference situations (Badia, Harsh, Coker, & Abbott, 1976; Hymowitz, 1973c). Hymowitz (1973c) used a free-operant shuttle box arrangement in which 10 animals were exposed to a VT 65-sec schedule of scrambled foot shock (.40 mA). For five of the animals, one side of the shuttle box was associated with signaled shock (100%), and the other side was associated with unsignaled shock (0%). For five other animals, one side of the box was associated with unsignaled shock (0%); on the other side, the CS preceded shock on 50% of the shock occasions.

The animals showed a marked preference for 100% signaled shock delivery over 0% or unsignaled shock. This was true of all five of the animals tested. However, a clear preference for the 50% signal over the 0% signal condition was not found. A signal that reliably indicated the presence of shock but not the absence of shock was not preferred over the no-signal condition.

Badia et al. (1976) used a changeover procedure (from unsignaled to signaled shock delivery) to answer a related question. Is changeover responding controlled by stimuli that reliably indicate the presence of shock or by stimuli that reliably indicate the absence of shock? When the CS precedes shock 100% of the time, the CS necessarily serves both signaling functions. When the probability of the CS preceding shock is varied, the signal function of the CS also is altered, depending on the manner in which the CS and the shock are programmed.

In one condition, all of the shocks were preceded by a CS. However, the probability of a CS being followed by shock varied from 1.0 to .02. Thus, at some CS–shock probabilities, the presence of the CS did not reliably indicate shock occasions, although the absence of the CS reliably indicated shock-free occasions. In this condition, the animals consistently changed over from unsignaled to signaled shock at each probability level; that is, animals readily selected the condition in which the CS dependably specified the absence of shock but not necessarily the presence of shock.

In a second condition, all of the CSs were followed by shock. Some shocks were not preceded by a CS, depending on the desired probability value. This is the same manner of programming the CS and the shock that was used by Hymowitz (1973a, 1973c). As the dependability of the CS as an indicator of the absence of shock decreased, the animals' preference for the CS condition decreased, even though the CS still reliably specified the presence of shock. These data are in close agreement with the preference data reported by Hymowitz (1973c) and with the suppression data for the group of animals exposed to the variable-interval shock delivery schedule (Hymowitz, 1973a, Experiment 3).

One other study also examined differential associations between the CS and shock (Nageishi & Imada, 1974). They presented an average of three shocks per session. For one group of animals, all of the shocks were preceded by a CS (100%); for another, two of the shocks were preceded by a CS (66%); for another, one of the shocks was preceded by a CS (33%); in a final group, none of the shocks were preceded by a CS (0%).

Nageishi and Imada (1974) reported that the degree of response suppression was directly related to the degree of shock predictability, the least suppression occurring in the 100% condition and the most in the 0% condition. In their study, the presence of the CS reliability indicated the availability of shock in the 66% and 33% conditions. However, the absence of the CS did not reliably indicate the absence of shock. Based on the preference data cited earlier (Badia et al., 1976; Hymowitz, 1973c), Nageishi and Imada's (1974) findings are somewhat surprising. The preference data suggest that the utility of the CS derives from its specification of shock-free, not shock, occasions.

Nageishi and Imada's (1974) findings are in close agreement with Hymowitz's (1973a) findings for fixed-interval shock delivery but not for variable-interval shock delivery. Although procedural and methodological differences between the studies prohibit direct comparisons, one cannot help but wonder whether the small number of shocks (three per session) delivered in Nageishi and Imada's study in some way accounts for some of the differences. For example, the delivery of the third shock may have signaled shock-free occasions.

Clearly, the percentage of occasions on which the CS precedes shock is an important determinant of response suppression during signaled and unsignaled shock delivery. Moreover, the manner in which the CS and shock are programmed is also an important factor. To gain a better understanding of the relationship between the predictability of shock and differential response suppression, further studies are required. One useful approach would be to investigate the differential sup-

pression of schedule-controlled and schedule-induced responding, perhaps within the same animal, under conditions in which the percentage of occasions on which the CS precedes shock is varied. The CS and shock also should be programmed so that the CS may dependably specify shock-free occasions or dependably specify shock occasions, but not both (cf. Badia et al., 1976).

Discriminability of Shock-Free Occasions

There are two important theoretical viewpoints from which to view data on signaled and unsignaled shock. According to Perkins (1968), the importance of the CS derives from the fact that it enables the animal to prepare for shock. According to Seligman (1968; see also Seligman, Maier, & Solomon, 1971), the CS is important because it specifies occasions in which shock is not available. Such shock-free occasions may allow the animal to relax (cf. Denny, 1971) instead of remaining in a chronic state of fear. The reinforcing effects of shock-free occasions have been demonstrated quite eloquently in studies of avoidance and shock-frequency reduction (Hineline, 1977).

Recent studies by Hymowitz (1976b, 1977b), in which animals were studied under mixed as well as multiple schedules of signaled and unsignaled shock, provide considerable support for the safety signal analysis. Multiple schedules contain discriminative stimuli that distinguish one component from the other. Mixed schedules do not. During multiple schedules of signaled and unsignaled electric-shock delivery, the animals may readily discriminate that component in which the absence of the CS is associated with the absence of shock. During mixed schedules, this discrimination is highly unlikely. Although both schedules are the same in that the CS is reliably associated with the presence of shock, they differ in that only during the multiple schedule is the absence of the CS clearly associated with the absence of shock.

To the extent that the preparedness value of the CS is the determining factor, one would predict differential response suppression during signaled and unsignaled shock for each schedule. To the extent that the discrimination of shock-free time is necessary for differential responding, differential response suppression is predicted for the multiple schedule but not for the mixed schedule.

The data (Hymowitz, 1976b, 1977b) clearly favor the safety signal hypothesis. Although differential suppression was found for the multiple schedule of signaled and unsignaled shock, responding during the components of the mixed schedule of signaled and unsignaled shock was not differentially suppressed. Responding was similarly suppressed during signaled and unsignaled shock delivery. These findings, as well as those of Hymowitz (1973a, 1973c) and Badia et al. (1976) referred to previously, strongly suggest that the discrimination of shock-free occasions, rather than shock occasions, is one of the key determinants of differential responding during signaled and unsignaled shock (see also Arabian & Desiderato, 1975).

Discussion

As noted previously, studies of response suppression during signaled and unsignaled electric-shock delivery uniformly support Seligman's (1968) original report of more response suppression during unsignaled than during signaled shock. Moreover, the generality of Seligman's (1968) original findings was successfully extended to include operant and adjunctive licking, a variety of shock delivery schedules, a wide range of shock parameters, and several different schedules of food delivery. In general, the findings on differential response suppression also are consistent with Seligman's (1968) safety signal hypothesis. In particular, studies that show that the predictability of shock-free occasions, not shock occasions, is a key determinant of differential responding (Hymowitz, 1976b, 1977a) lend strong support to the safety signal hypothesis.

It is also important to note that it is highly unlikely that the findings on differential response suppression are, in some way, due to procedural or methodological artifacts. All of the studies mentioned in this review employed scrambled electric-shock delivery. Hence, modification of shock by postural adjustment was minimized. Some of the studies

(Hymowitz, 1973a, 1976b) used response-dependent shock, and the response lever was included in the shock circuit. With such a procedure, it was nearly impossible for the animal to escape shock once it was produced. Yet, much more response suppression was found during unsignaled than during signaled shock. In addition, Hymowitz (1976b, 1977b) showed that responding was suppressed as much during the signaled as during the unsignaled shock component of mixed schedules of shock delivery. If the animal had used the preshock stimulus as a discriminative cue for an avoidance–escape response, one would have expected less suppression in the signaled component of the mixed schedule. To the contrary, the animals seemed not to benefit from signaled shock delivery unless the absence of the signal was reliably associated with the absence of shock. Such findings are highly compatible with the safety signal hypothesis.

The literature review also revealed a number of variables that seem to influence differential response suppression during signaled and unsignaled shock and choice of signaled over unsignaled shock in the same manner. Both depend on the discriminability of shock-free occasions and the intensity of shock. The agreement between studies of choice and studies of response suppression is so great in some instances that the confidence one may place in the reliability of the data is markedly enhanced. Despite the serious criticisms leveled at much of the choice literature, the good fit between the choice and suppression literature enhances our confidence in the findings that animals do prefer signaled over unsignaled shock and that the variables that control the choice of signaled shock also determine the differential suppression of responding during signaled and unsignaled shock.

Although the data generated during the past decade are generally consistent with the safety signal hypothesis, some of the more recent findings suggest the need for possible revision or extension of the hypothesis. It is not clear, for example, why differential response suppression should occur for any given animal at one intensity of shock or for one kind of behavior and not at another intensity or for another behavior. The discriminability of shock-free occasions plays an important role in determining differential responding, but it is not the only variable of importance. As in most other analyses of response suppression, the resistance of responding to the suppressive effect of shock depends on the interplay of a host of food-related and shock-related behaviors. As additional analyses of the variables that influence differential response suppression become available, it may be possible to fit the safety signal hypothesis within a broader theoretical context. *Safety* and *danger* are relative terms, lacking in precision and clarity. As additional data emerge, it may be more fruitful to analyze the suppression of responding during signaled and unsignaled shock in terms of interactions among the signaling of shock, the motivational state of the organism, the nature of the food and shock schedules, the strength of the response under study, and the past experimental history of the organism. Viewed in this manner, safety and danger are but two of the many variables that determine the suppression of responding. Thus, the time may be rapidly approaching when the safety signal hypothesis will lose its appeal as an explanatory mechanism. However, as shown in the present literature review, the safety signal hypothesis has served us well. It has proved to be a useful organizing principle for a considerable body of experimental literature and has laid the foundation for our current knowledge of the effects of signaled and unsignaled aversive events on behavior.

Infant Crying as an Elicitor of Parental Behavior: An Examination of Two Models

Ann D. Murray
Macquarie University, Sydney, Australia

Two models of the compelling nature of the infant cry and its effectiveness in eliciting caregiving behavior are examined. The first model is that of the cry as a releaser of parental behavior. It is suggested that a good fit between the available data and this model depends upon broadening the classical definition of the releaser concept to include motivational factors in a manner advocated by some of the modern ethologists. A model of the cry as an activator of motives of an egoistic or altruistic nature is also examined. This model, based on Hoffman's theory of altruistic motivation, contributes to an understanding of both the compelling releaserlike effects of the cry as well as the wide variations observed within and between cultures in the nature and extent of caregiver responsiveness. It is further argued that altruistic behavior toward crying infants in particular must be viewed within the specific context of ontogenetic processes that enhance the attractiveness of the young for adult caregivers.

It is part of the folklore that the cry of a young infant is a compelling stimulus. There is an urgency associated with the cry that makes a response to it obligatory (Ostwald, 1963). In addition to its purely motivational qualities, the cry evokes intense emotional reactions that can be either of a constructive or of a destructive nature. It is capable of evoking strong feelings of concern and protectiveness on the one hand or of extreme hostility on the other (Ostwald, 1963). The action taken in response to the cry can likewise consist of nurturant acts or murderous ones (Stone, Smith, & Murphy, 1973, p. 1002).

In the theoretical and empirical analysis that follows, two conceptualizations of the mechanisms by which the cry has its powerful impact are examined. First, the question of whether the cry can be considered a releaser of parental behavior is discussed with reference to claims for its evolutionary significance, the physical nature of the stimulus, its signal value, parental responses to it, and possible receptor mechanisms. Subsequently, a model is presented that views the cry as a graded signal that activates motives of either an altruisitc or an egoistic nature. Last, some factors influencing the ontogeny of parental behavior are examined. For purposes of this analysis, the focus is restricted to crying in early infancy when the infant is not physically mobile and is totally dependent on a caregiver for the satisfaction of his or her needs.

The Cry as a Releaser of Caregiving Behavior

Evolutionary Significance of the Cry

Within the framework of the attachment theory formulated by Bowlby (1969) and Ainsworth (1969), it has been suggested that the infant cry may serve as a releaser of caregiving behavior. Crying is considered by these theorists to be an attachment behavior that promotes proximity to or contact with the

caregiver, usually the mother. Using an ethological perspective, these theorists have hypothesized that attachment behaviors such as crying, smiling, and following originally evolved to perform a protective function by bringing the infant into close proximity with the mother, who could then defend him or her against predators and other dangers. Although such close proximity between mother and infant is not necessary to ensure protection in our present society, Bowlby and Ainsworth argued that babies are nevertheless genetically programmed to cry when out of contact or distressed and that their behavior is adapted to the prototype of a responsive caregiver.

To support his thesis concerning the evolutionary adaptedness of close mother–infant proximity and sensitivity to crying, Bowlby cited indirect evidence. He argued that species-typical characteristics are adapted to the environment in which the species evolved. For *Homo sapiens,* it is especially difficult to determine the adaptive significance of characteristics because people have modified their environment so drastically from that in which they originated. The kinds of evidence used to support his theory include comparative studies of animals and anthropological studies of contemporary societies that exist in environments that are least modified from the "environment of evolutionary adaptedness." Since the publication of Bowlby's work in 1969 three recent studies have provided additional support for his theory.

Konner (1972; Devore & Konner, 1974) studied the rearing patterns of a hunter–gatherer society in Botswana. He argued that 98% of the evolutionary history of *Homo sapiens* took place in a hunter–gatherer economy and that very little evolution has occurred since then. He hoped to be able to highlight the adaptive consequences of the rearing pattern he found with reference to the environmental selective pressures associated with this preagricultural nomadic existence. A major feature of the rearing pattern he found was that there was virtually continuous contact between the mother and her infant. Infants were carried in a sling on the mother's side or on the hip. The feeding pattern was also described as continual in that infants were nursed at least twice an hour for a period of 30 sec to 10 min. Konner reported that infants rarely cried because mothers could anticipate hunger by interpreting more subtle proximal cues such as bodily movements, facial expressions, and so on. In fact, the cry was treated as an emergency signal and was responded to as such with an average latency of 6 sec. Note that this contrasts sharply with the practice in Western cultures in which response is delayed for from 5 to 30 min (Bernal, 1972) and young infants cry an average of 1 to $2\frac{3}{4}$ hours a day (Bernal, 1972; Brazelton, 1962). According to Konner, the adaptive consequences of the hunter–gatherer rearing pattern were twofold. Close proximity served as a protection from predators and other dangers in early infancy and fostered strong attachments to adult models of hunting and gathering skills.

Although the comparative evidence presented by Bowlby has been criticized for its heavy reliance on studies using the rhesus monkey (Dolhinow & Olson, Note 1), support has been provided for Bowlby's theory by the findings of Blurton-Jones (1972) in his survey of a wide variety of mammalian species. Blurton-Jones asked whether human infants and their mothers are adapted to relatively continuous contact (the pattern common among hunter–gatherer societies and Old World monkeys and apes) or to relatively discontinuous contact as exemplified by the European and American style of rearing. To answer this question he surveyed a wide variety of mammals to determine what anatomical, physiological, and behavioral features correlated with the two rearing patterns of caching and carrying. He then applied the correlations found in animals to the human mother and infant to predict whether humans evolved as a caching or a carrying species. In caching species such as the tree shrew, the young are left for long periods in hiding places while the mother forages for food, and feeding is at widely spaced intervals. In carrying species, the young ride on the mother, and feeds are closely spaced.

The evidence that human beings evolved as a caching species was not convincing be-

cause (a) the young would have to remain silent until the mother returned so as not to attract predators by crying, (b) cached young do not urinate or defecate without maternal stimulation as this too would attract predators, and (c) the young would have to possess mechanisms of thermoregulation. None of these conditions were satisfied for the human infant.

The evidence for carrying, however, strongly favored continuous contact. Three arguments were advanced based on milk composition, sucking frequency, and the duration of feeding. The composition of the mother's milk correlated with the schedule of feeding such that in widely spaced feeders, there was a high protein and fat content, whereas in continuous feeders, there was a low protein and fat content. For example, the tree shrew, which feeds every 48 hours, had a high protein and fat content compared with the higher nonhuman primates, which are continuous feeders. Human milk was found to be identical in fat and protein content to that of the continuous-feeding anthropoid apes. Similarly, sucking frequency correlated with feeding frequency and milk composition. Animals that fed the least often sucked the fastest, and fast sucking was associated with a high protein and fat content in the mother's milk. The slow sucking rate in human infants is, therefore, adapted to a pattern of continuous contact. The third piece of evidence was that widely spaced feeders fed for a short duration. For example, the duration of feeding for rabbits was 4 to 5 minutes once every 24 hours. The time spent each day in feeding for human infants was found to be comparatively long, suggesting adaptation to the continuous-feeding pattern.

As further support for the hypothesis that human infants are adapted to the prototype of a responsive mother, Bell and Ainsworth (1972) have claimed that prompt maternal responses to crying early in the first year have adaptive outcomes for infants. They found that responsiveness to crying in the first half year led to a decrease in the frequency and duration of crying in the second half year. In addition, those infants whose mothers had responded promptly to their cries early on were less likely to use crying in an instrumental manner at 1 year of age and were more likely to develop other social signals such as bodily gestures, facial expressions, and vocalizations to communicate with their mothers. According to Bell and Ainsworth, their findings indicate that crying is at first expressive and indiscriminate and that only toward the end of the first year does crying become "goal corrected" and used with the intent to influence others.

If the infant cry is an adaptive species-characteristic behavior that evolved as an emergency signal, one might expect to find reciprocal mechanisms in caregivers that ensure a response in kind to the cry. The consequences of an appropriate response for the infant relate to his or her chances of survival; an appropriate response is adaptive for the parent also because the infant's survival ultimately contributes to the parent's reproductive success. In cases such as this, in which contact between conspecifics is adaptive to both, the sender of the signal and the receiver of the signal will be mutually adapted to each other (Eibl-Eibesfeldt, 1975). In this vein, it has been suggested that the infant cry and other attachment behaviors such as smiling may operate as sign stimuli that release parental behavior (Bowlby, 1958).

The Releaser Mechanism

Since Lorenz's original observations of releasers in the 1930s, examples of this form of adaptive mechanism have been described in many species (Eibl-Eibesfeldt, 1975). A sign stimulus is a simple, conspicuous, and specific stimulus that acts figuratively as the key that unlocks a stereotyped motor action (often referred to as a fixed action pattern). The receiver of the key stimulus is said to possess an innate releasing mechanism (IRM), the hypothesized neural receptor center for receiving and filtering afferent impulses produced by the key stimulus. Releasers have been found to regulate interactions between prey and predator, between sexual partners, between sexual rivals, and between parent and young in many species (Eibl-Eibesfeldt, 1975).

Although the infant cry is often casually likened to a releaser, no formal assessment of whether it fits the model has ever been carried out. Much effort has been put into describing the physical characteristics of the stimulus, but little effort has been made to determine whether and/or which key features affect parental responses. Often the question of whether the cry acts as a releaser is linked with the issue of whether different cry types, for example, for pain versus hunger, are recognizable and how these cry types differ in physical characteristics. In the ensuing paragraphs, an attempt is made to assess the "goodness of fit" of the model of the cry as a releaser.

Although it is recognized that the releaser concept as originally proposed by Lorenz (1937) has recently come under attack (cf. Hinde, 1974; Klopfer, 1974), the classical view of the IRM has been adopted here for heuristic purposes. The following list of the basic characteristics of releaser systems is derived from Eibl-Eibesfeldt (1975), who provides the modern expression of the Lorenzian ethological view.

1. The basis for recognition of the key features of the stimulus and for the performance of a response is said to be *innate* in that the system is functional in inexperienced animals that have had no prior experience with the stimulus.

2. Sign stimuli are made up of simple, conspicuous, and specific cues. It is even possible to trick an animal into responding to simplified (artificial) models of the stimulus in an unnaturalistic context.

3. Sign stimuli exhibit the phenomenon of *heterogeneous summation*. The same response can be elicited by several different and independent cues that combine additively to increase the effectiveness of the sign stimulus.

4. The optimal stimulus is often unrealistic. By exaggerating key features of the stimulus, a "supernormal" stimulus is produced that is more effective than a natural stimulus.

5. The response to the stimulus is a stereotyped behavioral response.

6. This stimulus–response specificity is accomplished through a neural receptor–effector system in which afferent impulses from the senses are linked with efferent impulses from motor centers leading to the occurrence of fixed action patterns.

Each of these characteristics is reviewed in relation to the available literature on infant crying.

Innateness of Stimulus Recognition

For all practical purposes, the criterion of *innateness* cannot be examined for adults who, even if never exposed to an infant's cry, cried as infants themselves and have had the experience of crying during their life spans. The only research that possibly bears on this issue are the studies of contagious crying in newborns conducted by Simner (1971) and Sagi and Hoffman (1976). Simner found that infants tested at about the age of 70 hours cried more in response to a tape recording of a newborn cry than they did to either the cry of a 5½-month-old infant or to two artificially produced sounds (a computer-synthesized cry designed to contain features similar to the newborn cry and a series of white noise bursts included to control for the nonvocal properties of the cry). Furthermore, a tape recording of the infant's own cry produced more crying than the cry of another newborn. Contagious crying was found to be greater among female than among male infants. Simner speculated that imitation of sounds not very discrepant from those with which the infant was already familiar could account for the greater effectiveness of the two newborn cries when compared with the cry of the older infant and with the artificial sounds.

Sagi and Hoffman (1976) replicated Simner's (1971) results with younger infants (average age was 34 hours) using only the newborn cry and the synthesized cry from Simner's tapes. The newborn cry elicited more crying than did the synthetic cry and a control period of silence. The sex difference in contagious crying was also replicated. The authors took issue with Simner's original cognitive interpretation of these findings, because the contagious crying they observed appeared to be indicative of genuine distress rather than just a vocal response in imitation of a vocal stimulus. They interpreted their

results in terms of inference theory: Distress cues from another person evoke associations with the observer's own past distress and result in a distressed state in the observer. This interpretation rested on a classical-conditioning paradigm. Because they felt that evidence for conditioning in 1-day-old infants was weak, Sagi and Hoffman suggested that the distress response to another's distress could be innate.

The Cry as a Simple, Conspicuous Stimulus

Studies of cry sounds have been not only numerous but also inspired by many diverse interests on the part of investigators. These studies fall into two groupings: (a) detailed acoustical descriptions of cries and cry types inspired by the new technology of the sound spectrograph and other instruments (normative studies) and (b) research on the ability to recognize cry types (signal value studies).

Normative studies. Although there was one early attempt at an acoustical study of the infant cry (Fairbanks, 1942), most of the normative studies followed the invention of the spectrograph. These normative studies have established the temporal pattern of the newborn cry; it can be described as an expiratory cry that lasts .6 to 1.4 sec and is followed by a brief silence (.2 sec); it is sometimes followed by a brief inspiratory whistle (.1 to .2 sec) and by another brief period of rest (.2 sec) before another expiratory cry begins (Sedlackova, 1964; Truby & Lind, 1965; Wolff, 1969). The fundamental frequency of the expiratory cry is 400 Hz on the average, with the inspiratory whistle having a somewhat higher (550–600 Hz) frequency (Truby & Lind, 1965; Wolff, 1969). There is often a rising–falling pattern of frequency, for example, an expiratory cry of .6 sec in length might begin with a fundamental frequency of 300–350 Hz for .2 sec, rise to 500 Hz for .2 sec, and fall to 300–200 Hz for .2 sec (Truby & Lind, 1965; Wolff, 1969). The loudness of the cry is about 80 dB when measured 12 inches (30.5 cm) from the baby's mouth (Ringel & Kluppel, 1964). There are wide individual differences among babies in the characteristics of their cries, but individual cry patterns have been found to be stable for each infant (Ringel & Kluppel, 1964).

Before the emphasis in cry studies shifted to the description of cry types associated with different causes or emotions, Truby and Lind (1965) distinguished three general types of expiratory cries based on their inspection of hundreds of sound spectrograms. These types appeared to be associated with the intensity or effort put into the cry. The cries they analyzed were obtained from 1- to 12-day-old infants who were all pinched to provide a standard stimulus to cry. The three cry types were phonation, dysphonation, and hyperphonation. They called the basic cry pattern phonation because of its harmonic structure and the symmetry and smoothness of the spectrogram and intensity pattern. Phonated cries did not give the impression of great distress or discomfort. Dysphonated cries were effortful performances in which turbulence or noise caused by overloading at the larynx obscured the harmonics of the basic cry pattern. Hyperphonated cries were characterized by an abrupt shift from or to a very high pitch of up to 2000 Hz, were whistle-like, and were caused by strain and constriction of the vocal apparatus. Hyperphonation often occurred concurrently with dysphonation for the most vociferous response to discomfort. Strain during egression was usually followed by hyperphonation during ingression—the inspiratory whistle described earlier.

The major attempts to differentiate acoustically among cry types of newborns according to their cause or underlying emotion have been made by Wolff (1969) and Wasz-Hockert, Lind, Vuorenkoski, Partenen, and Valanne (1968). Wolff distinguished three major cry types: the hunger cry, the mad or angry cry, and the pain cry. The hunger cry had no causal relation with hunger according to Wolff but was really just a basic rhythmical pattern. The basic pattern that Wolff described is similar to the phonated cry in Truby and Lind's classification. The inspiratory whistle that Wolff found to occur within the basic cry pattern can be likened to the hyperphonated cries of the latter in-

vestigators. Wolff's mad or angry cry was characterized by turbulence due to an excess of air being forced through the vocal cords. This mad or angry cry was, then, synonymous with the dysphonated cry described by Truby and Lind. Wolff's third cry type, the pain cry, was differentiated not on the basis of acoustical attributes, but on the basis of the temporal pattern of the first two or three expiratory cries following application of a painful stimulus. Wolff's pain cries were recorded during the general hospital practice of pricking the neonate's heel to take a blood sample. This painful stimulus probably produced more discomfort than the pinch used by Truby and Lind. The cardinal features of Wolff's pain cry were (a) a sudden onset of loud crying (as opposed to a gradual buildup for the hunger or basic cry), (b) an initial long cry (as long as 4 sec compared with 1 sec or less for the basic cry), and (c) an extended period of breath holding after the initial cry (for as long as 7 sec). In Wolff's study, the pain cry settled down to the basic temporal pattern after two or three long expiratory cries. Except for pointing out the temporal pattern of the cry following a very painful experience, Wolff's formulation adds little to that provided by Truby and Lind. Wolff himself disavowed that the basic cry had a causal connection with hunger, and the mad or angry cry can be described as just a more effortful performance indicative of greater discomfort, as in Truby and Lind's formulation. For convenience in the following discussion of research concerning cry types, the labels used by the authors concerned, for example, "hunger" cry, have been retained, although the implied causal connections may be questionable.

Following what appeared to be a rather simple and appealing description of the basic cry pattern (phonation) with various superimposed features indicative of effort (dysphonation, hyperphonation, and length of the expiratory cry), Wasz-Hockert et al. (1968) performed a multivariate study of characteristics of cry types based on 11 attributes: length of the expiratory cry, pitch (minimum, general, and maximum), shift (cf. hyperphonation), voice (voiced, voiceless, and half voiced; cf. phonation vs. dysphonation), melody types (rising–falling, rising, falling, flat, and no melody), continuity of signal, glottal plosives, vocal fry, nasality, tenseness, and subharmonic break. Using examples of birth, hunger, and pain cries, a multiple discriminant function analysis was used to arrive at decision rules for classifying cries into types. A rising–falling melody was associated with hunger cries; any melody other than rising–falling and with a length of more than 1.5 sec was a pain cry, and melodies other than rising–falling with lengths of less than 1.5 sec were birth cries. Although shift (hyperphonation) and voice (phonation vs. dysphonation) did not contribute substantially to the classification based on the multiple discriminant function analysis, the authors mentioned that shift occurred most frequently with pain cries, that birth cries were usually voiceless, and that hunger and pain cries did not differ in voice. Given that so few of the measures used were predictive and that the major bases for differentiation could be said to be the length of the signal and types of phonation (because the scoring of melody was confounded with voice, i.e., voiceless sounds could not be scored for melody), the Wasz-Hockert results seem to indicate that the cries were not uniquely different according to what caused them but rather differed in intensity according to the degree of discomfort experienced by the infant. One might expect that a baby experiencing hunger will be less distressed than one experiencing birth or pain. The authors themselves noted that hunger cries when left a long time unattended began to resemble pain cries.

Signal value studies. The studies conducted to determine whether different cry types are recognizable are fraught with methodological differences that make conclusions difficult to reach. Some studies have used multiple-choice techniques, others have not. Some have controlled for the durations of the cry sequences, others have not. One has used single expiratory cries, thus eliminating information provided by the temporal pattern of cries. The choices of cry types to be identified and the methods of evoking the cries have differed. In some studies, investigators,

have narrowed their selection of cries only to cries that they say are "typical" of their type.

The landmark study of this type was conducted by Sherman (1927). Without the benefit of magnetic recording devices, he had to make live presentations of his stimuli. Groups of observers separated from the infants by a screen listened to cries elicited by four stimuli: hunger, sudden dropping, restraint of the head and face, and sticking with a needle. Observers were exposed to each cry for approximately 10 to 15 sec. With no predetermined cry-evoking categories provided, the 23 observers exhibited little agreement and mentioned a total of 12 emotions including hunger, pain, fear, colic, rage, and so forth. Sherman noted that when observers were allowed to listen for a longer period of time (2 to 3 min), they were able to distinguish between cries caused by the application of an external stimulus and cries associated with an internal organic condition (hunger or colic), as the latter tended to be more prolonged than the former.

The strongest criticisms of Sherman's work have been voiced by Izard (1971) and Ekman (Ekman, Friesen, & Ellsworth, 1972). According to Izard, the most remarkable thing about Sherman's work is that no one questioned why observers should be expected to differentiate among emotional reactions that all included distressful crying. Izard considers crying to be primarily the expression of one emotion: distress–anguish. This emotion is equivalent to what Darwin (1872/1965) described as the emotion of suffering. Ekman criticized Sherman for failing to distinguish between judgments of emotions and judgments of events and for treating responses of rage and anger as separate and pain and hurt as separate when these are synonyms. Further, he echoed Izard's concern that all four situations may have elicited the same emotion. Whereas Ekman suggested that the predominant emotion expressed may have been anger–rage based on the frequency with which observers nominated this emotion, Izard argued that distress would have predominated over angry emotions.

The next series of studies was conducted by Wasz-Hockert and his colleagues. In the first study (Wasz-Hockert, Partenen, Vuorenkoski, Michelsson, & Valanne, 1964), nurses listened to six examples of "typical" cries of four types: birth, hunger, pain, and pleasure. The length of the cry samples varied from 5 to 17 sec with a mean length of 12.3 sec. Nurses correctly identified an average of 16 out of the 24 cries using a multiple-choice method in which they were told to select from among the four cry types. The poorest score of 11 was significantly different from a chance score of 6.

In the next study (Wasz-Hockert, Partenen, Vuorenkoski, Valanne, & Michelsson, 1964), these investigators used the same method to test males and females who were experienced and inexperienced caregivers. Experienced women included mothers, children's nurses, pediatricians, and midwives. Experienced men included fathers and pediatricians. Inexperienced men and women had not looked after infants from 0 to 2 years in age for as long as 2 weeks. Experienced women correctly identified significantly more cries than inexperienced women. Experienced men did not significantly differ from inexperienced men. The lowest group mean was still significantly different from a chance level. Although the authors did not test for a sex difference, their data indicate that men were considerbly less accurate than women. Surprisingly, fathers and pediatricians scored lower than women with no experience. In addition, the easiest cry to identify was the pleasure cry, which was identified correctly almost 100% of the time. The hardest to identify was the birth cry.

In a later study with only women as subjects (Wasz-Hockert et al., 1968), a slightly different method was used. Six examples of each of the four cry types were randomly selected from the pool of expiratory cries used in the multiple discriminant function analysis described earlier. Each single expiratory cry was repeated seven times. Again, experienced women were found to perform more accurately than inexperienced women, and the lowest group score was higher than chance level. Again, the pleasure cry was easiest to identify and the birth cry the hardest. Birth was often confused with hunger and pain, and

hunger and pain were often confused with one another. The most poorly recognized cries, the authors claimed, were not representative of their type.

Muller, Hollien, and Murry (1974) criticized the Wasz-Hockert studies on a number of grounds. In particular, they felt that the inclusion of birth and pleasure cries was inappropriate and that Wasz-Hockert should have controlled for sample duration. They reported evidence that subjects could not correctly identify cries evoked by pain stimulation (snapping a rubber band against the skin), auditory stimulation (clapping together wooden blocks), and hunger stimulation (withdrawal of feeding). Note that this last cry was evoked differently from previous studies in which naturally occurring hunger cries were recorded before a meal. Mothers of the infants recorded, and a group of mothers of infants of comparable age listened to, two 15-sec segments of crying for each stimulus. Neither group of mothers was able to identify correctly the cry-evoking situation in a multiple-choice situation. Muller et al. concluded that the acoustic characteristics of cries carry little perceptual information about the cry-evoking situation, that the cry generally acts only to alert the mother, and that judgments of the causes of crying in the home are based on additional environmental cues.

Interest in whether cry types are identifiable has stemmed from two sources. This issue is of importance not only to those who have been concerned with the ability to correctly identify emotional expressions of others but also to those who have been tracing the continuity of development of infant sounds for communication from crying to babbling and finally to language (e.g., Irwin, 1948; Lynip, 1951; Winitz, 1960). It is possible that this intense concern represents an overintellectualization of the problem. On the basis of the confusion in the literature over different cry types, their unique characteristics, and their identifiability, it is more likely that certain attributes relate to the intensity of discomfort or distress felt and that any accuracy of identification according to evoking situation is due to a correlation between the intensity of the cries and observers' prior notions about the intensity of negative emotion associated with particular cry-evoking situations. Hunger builds up slowly and is ordinarily not as distressing an experience as pain for adults; therefore, raucous cries with sudden onsets are classified as due to pain and melodious cries with slow buildups as due to hunger. Indirect support for this hypothesis could be derived from the fact that there is no agreement in the literature on the causes of crying (see Aldrich, Sung, & Knop, 1945a; Aldrich, Sung, & Knop, 1945b; Brazelton, 1962; Illingsworth, 1955; Lakin, 1957; Lennane & Lennane, 1973; Stewart et al., 1954; and Wolff, 1969 for lists and discussions of possible causes of crying), and therefore one would not expect there to be agreement on the cry types associated with different causes.

Attempts to read into the cry more than is there may be partly a by-product of the distance maintained between parent and infant in our culture. Because this distance is so great as to preclude the use of more subtle communications (e.g., body movement and facial expression), great effort has gone into interpreting the only distal signal available to the infant—the cry. And further, because psychological needs (e.g., for contact or cuddling) as opposed to physiological needs are often not considered legitimate and deserving of attention, there is a need on the part of the parent to differentiate between "real" cries and "fake" cries. Reading into cries differentiated signal values with a view to elucidating the beginnings of prespeech communicative competence also belies the discontinuity between crying and the development of communicative competence. For example, Bell and Ainsworth (1972) found that excessive crying was negatively related to the development of positive social communicatory skills. This point is further amplified in a later section when evidence that there are two distinct systems controlling the expression of voluntary and involuntary vocalizations in human beings is reviewed.

The question I have addressed in the present section is whether the cry is a simple, conspicuous stimulus with key features important for stimulus recognition. It can be argued that the key features that emerge in

this review of the extensive literature relate more to stimulus intensity than to stimulus recognition. Whether there are simple features that are essential for recognition would have to be determined by systematically varying the acoustic parameters of the cry and noting which cues are essential for identification of the sound as an infant cry. In results mentioned earlier, infants differentiated between a real newborn cry and a synthesized cry (Sagi & Hoffman, 1976; Simner, 1971). This may indicate, by the criterion that the organism can be tricked into responding to a simple model of a releaser, either that the cry is not a releaser or that the essential key features were overlooked in synthesizing the cry. On the other hand, casual observation provides evidence that adults are in fact frequently tricked by the cry of a Siamese cat even when it is out of context, for example, when no infant is expected to be in the vicinity of the listener, who is not even a highly motivated parent.

Principle of Heterogeneous Summation

According to the principle of heterogeneous summation, separate and noninteracting cues combine additively to produce stimulus recognition. For example, the male stickleback's fighting response to a rival male is elicited either by the red spot on the male's belly or by the head-down position of the rival male (Eibl-Eibesfeldt, 1975). However, when both cues are combined, the attack response is more reliably elicited, that is, the stimulus is more likely to be recognized.

It might be argued that there are separate key features that, when superimposed on the basic cry pattern, would be more likely to elicit parental responses. These key features might include dysphonation or turbulence, hyperphonation or a shift to high pitch, the length of the expiratory cry, and the suddenness of onset. In a small experiment, Wolff (1969), while conducting his naturalistic observations of infants, played a tape recording of the infant's basic hunger cry and, on a separate occasion, played a pain cry to measure the delay before the mother responded. He claimed that there was a dramatic difference in speed of response, with response to the pain cry being almost immediate. As the pain cry was likely to possess some of the markers of intensity mentioned above, Wolff's result may provide some evidence of heterogeneous summation.

Evidence for Supernormal Stimulation

Although no one has tried to produce a supernormal cry stimulus artificially to measure its effectiveness, studies of the cries of brain-damaged and other abnormal infants may be of relevance to this issue. During the past 10 years, Wasz-Hockert and his colleagues have compared the cries of normal infants with those of abnormal infants, including those with Down's syndrome, neonatal asphyxia, brain damage, hyperbilirubinemia, *cri du chat* syndrome, and mixed or unspecified pathology. These studies, summarized in two recent reviews (Vuorenkoski, Lind, Wasz-Hockert, & Partenen, 1971; Wasz-Hockert et al., 1968), have found that the cries of abnormal babies are higher or lower in pitch than normal cries, have greater variability, and have different temporal patterns marked by either shorter or longer cry durations and cry intervals. The cries of abnormal infants are said to be so unpleasant that they override differences in maternal style (Ostwald, 1973; Wolff, 1969). Nurses expend much energy to keep them quiet, or they stay out of earshot. The cribs of these babies are said to be often tucked away in the farthest corner of the nursery from the nursing station because the cries of these infants are so unbearable to listeners (Milowe & Lourie, 1964). The exaggerated acoustic features and temporal patterns of the cries of abnormal babies may constitute supernormal stimulation, but no research has been reported that systematically relates these features to the effect of these cry sounds on the listener.

Evidence for a Stereotyped Response

The question of whether the cry produces a stereotyped response can be dealt with in two parts: First, does the cry elicit a response, and second, is the response a stereotyped one?

It is clear from a number of studies conducted in Western cultures that the infant cry does not always elicit a response from the caregiver. Bell and Ainsworth (1972) found that primiparous mothers of infants from 0 to 3 months of age ignored a median of 46% of crying episodes. The most responsive mother ignored only 4% of crying episodes and the least responsive ignored 97% of crying episodes. However, lower estimates have been provided by Moss and Robson (Note 2) and Bernal (1972), who found that an average of 17% to 18% of the cries of firstborns were ignored. Mothers of second borns in Bernal's sample ignored fewer crying episodes (8%). The discrepancies between Bell and Ainsworth's estimate and the estimates of the other investigators could be due to the former investigators' having computed a median rather a mean, to different definitions of crying episodes (e.g., Moss and Robson used fusses rather than cries), or to different data collection methods (observational methods vs. diaries).

For those cries that were attended to, the duration of the delay or the latency of the response was reported in two studies. Bell and Ainsworth (1972) reported that mothers delayed a median of 3.83 minutes per hour with a range of 2 minutes to 9 minutes. Bernal (1972) reported that roughly two thirds of the cries were responded to within 10 minutes but that response was delayed for from 10 to 30 minutes for one third of the cries. The smaller range reported by Bell and Ainsworth may be a function of their having computed the duration of the delay per hour rather than per episode.

The Western pattern of often ignoring the cry and delaying response to it contrasts sharply with reports mentioned previously that mothers in hunter–gatherer cultures never ignore infant cries and respond with an average latency of 6 sec (Devore & Konner, 1974). In fact, the findings of Bernal on mothers' unresponsiveness to crying in a Western culture led Richards (1974) to remark that "the important lesson for the infant is how little effect his crying has on his caretakers" (p. 90). On the other hand, several other pieces of evidence would seem to indicate that Richards may have overstated the case. In a small experiment, Moss and Robson (Note 2) wanted to test whether mothers of $3\frac{1}{2}$-month-old infants would respond to a button that lit up (on a schedule prearranged by the experimenters) to indicate that their infants were crying in another room. The investigators had previously observed these mother–infant pairs in the home and had found that mothers responded to 77% of their infants' cries. However, in the button experiment, only 13 out of the 54 mothers responded to the lighted button (as reported by Harper, 1971), a response rate of only 24%.

That the *sound* of the cry may be necessary to convey a sense of urgency was hypothesized by Lenneberg, Rebelsky, and Nichols (1965) in their study of infants born to deaf parents. They reported that deaf parents were not compelled to attend to their crying infants even if they could see the distressed state that their infants were in. It was as though some deaf parents could not tell whether their infants were in distress by looking at them. It appears that the cry may be a necessary though not a sufficient condition for a response in our culture and that a cognitive awareness of distress without the urgency conveyed by the sound itself is ineffective in eliciting a response.

Turning now to whether motor responses to cries can be described as stereotyped, the most frequent intervention in the early months has been found to involve close physical contact (picking up and holding or feeding). Close physical contact accounted for at least half of the interventions in the Bell and Ainsworth (1972) study with primiparas. Of those crying bouts that were attended to, Bernal (1972) observed that 69% resulted in feeding by primiparas and 89% resulted in feeding by multiparas. Furthermore, interventions involving physical contact were 80% effective in soothing the infants in Bell and Ainsworth's sample. These results are consistent with those reported by Korner and Thoman (1970), who found that crying newborns were most effectively soothed and brought to a visually alert state by contact that was combined with vestibular stimulation and an up-

right posture. Over time, however, noncontact interventions such as approaching, vocalization, and other social stimulation became increasingly effective and were more frequently used by mothers (Bell & Ainsworth, 1972; Moss & Robson, Note 2).

Although the studies reported indicate that by far the majority of cries are followed by nurturant responses involving close physical contact, it must not be overlooked that crying is also one of the major precipitants of abuse for children under 12 months of age. In one study of infants battered by their parents, excessive crying was given as the reason for battering by 80% of the parents of infants less than a year old (Weston, 1968).

One could argue, however, that the cry may not always be a sufficient stimulus to elicit any response in our culture, let alone a nurturant response, because of anomalies of development. Lorenz (1965) has stressed that fixed action patterns are very sensitive to "bad rearing" that can cause the disintegration of releasing mechanisms. If the parental attachment system develops optimally under conditions of close parent–infant contact and minimal crying, then a pattern involving little contact and excessive crying may result in nonfunctional or maladaptive responses to the releasing stimulus of crying. In this connection it is worth noting that sensitivity to crying signals typically occurs within a larger cultural pattern of rearing characterized by close mother–infant contact, prolonged breast-feeding, and wide spacing between children. In a survey of 222 cultures, Mead and Newton (1967) found that cultures clustered basically into two types—those with a developed and those with a muted transition between delivery of the infant and the establishment of total physiological separateness. In contrast to the close contact pattern in cultures with the developed transition period, cultures exhibiting the muted transition period, primarily the industrial nations, were characterized by mother–infant separation in the hospital, early weaning, infrequent feedings, a great amount of crying with delayed parental response, and the prevalence of cribs, playpens, and other devices that maintain the baby at a distance and often out of sight of the mother. Because close mother–infant contact, sensitivity to crying, child spacing, and prolonged breast-feeding appear together so frequently in many types of primitive and traditional cultures, Mead and Newton suggested that "there may be strong mechanisms in this interrelation of patterning" (p. 186).

Receptor Mechanisms for the Cry

Lorenz's releaser formulation has inspired researchers to search for the underlying neural mechanisms ("the Holy Grail") involved in stimulus recognition (Brown, 1975). Consistent with a recognition model, researchers of biologically significant sounds have looked for evidence of specialized receptor apparatuses, processing modes, or feature detection capabilities (Wordon & Galambos, 1972). Generally, the search has focused on filtering mechanisms or templates within the auditory processing system. Controversy exists over whether templates consist of one "pontifical" cell or an ensemble of neurons (Wordon & Galambos, 1972) and over whether filters are located centrally or peripherally in the sense organs (Brown, 1975).

Although little neurological research of this nature has been conducted with primates and none with humans, there is a case reported in the literature (Mark & Ervin, 1970) of a teenager with a brain dysfunction who murdered her two sisters when they were babies. When tape recordings of infant crying were played to her, seizurelike activity was recorded in part of her limbic system (amygdala), and the teenager reported a very angry and floating sensation that lasted for several minutes after the cry was turned off. The limbic system is typically considered the "seat of the emotions" (Gellhorn, 1968), but our knowledge of it is limited. It is not clear whether the electrical responses evoked by the cries were determined by general state changes or by the specific acoustic features of the stimulus (Wordon & Galambos, 1972). Relevant to this issue but discussed more fully in a later section is McClean's (1973) suggestion that there may be functional areas in the limbic system that control emotions that guide species-typical behaviors.

Evaluation of the Model of the Cry as a Releaser

From the preceding review of the literature, it is evident that whether one accepts the releaser model of the cry's impact depends on how strictly one interprets the releaser concept. The evidence that most strongly supports the view of the cry as a releaser includes the finding of contagious crying in newborns, the suggestion that deaf parents do not exhibit an urgency about responding to crying, and the near universality of interventions that involve close physical contact. On the other hand, the cry signal does not appear to be a simple and discrete stimulus with a single meaning, but rather its meaning depends upon intensity cues and contextual factors. Cross-cultural variability in responsiveness to crying and the frequent citation of crying as the major factor precipitating abuse suggest that an appeal to additional, though perhaps not incompatible, mechanisms might further increase our understanding of the cry's impact on adults.

Because the releaser formulation originated with observations of invertebrates and lower vertebrates such as insects and frogs, it has been suggested that the IRM *sensu stricto* is not a useful concept when applied to higher vertebrates and particularly to primates (Wilson, 1975). Lorenz (1965), while retaining a fairly strict definition of the concept, has argued for the existence of phylogenetic vestiges of releasing systems in higher organisms (IRMs disintegrated by learning or higher development), but his application of the concept to human behavior in the popular book *On Aggression* (Lorenz, 1966) has been criticized (Piel, 1970).

The approach of a number of comparative psychologists has been to suggest the abandonment of the releaser concept altogether. They point out, for example, that the concept underestimates the role of experience in the ontogeny of fixed action patterns (Lehrman, 1970), that these behaviors are often not as fixed or stereotyped as once thought (Klopfer, 1974), and that the IRM is not a unitary mechanism that corresponds to a discrete center in the central nervous system (Hailman, 1970).

Rather than abandoning the releaser concept, others have dealt with the restrictiveness of the model by altering its definition to extend its meaning. Tinbergen (1948), for example, argued that sign stimuli are not always characterized by simple key features and, furthermore, that releasers need not elicit full-blown motor patterns but only minor elements of behavior or even internal reactions. Also in this tradition, Hinde (1974) suggested that there is a continuum ranging from fixed action patterns that are stable or relatively unaffected by experience to behavior patterns that are labile; because, in this view, most behaviors are affected by both heredity and environment, the question of whether a behavior is *innate* or *acquired* is unanswerable.

The tendency in higher mammals and primates is away from elementary sign stimuli toward signals that do not convey single fixed messages but are graded in intensity and derive their meaning from both intensity cues and contextual factors (Wilson, 1975). For this reason, a model that implicates motivational and cognitive influences in responses to crying is presented in the next section. It should be noted, however, that this model may not be incompatible with the broadened *social releaser* concept used by the English ethologists (e.g., Hinde, 1974; Tinbergen, 1948), who, unlike the ethologists in the classical tradition (cf. Eibl-Eibesfeldt, 1975), tend to view IRMs as motivational entities. Like the releaser model, this cognitive–affective approach can be described broadly as ethological in that it capitalizes upon Bowlby's suggestion (1969) that the cry's impact is releaser-like and that adults' reactions to it may be phylogenetically adapted.

The Cry as an Activator of Emotion

In this section, a model of the cry as an activator of emotions of either an egoistic or an altruistic nature is examined. First, an analogy is drawn between the infant cry and the graded signaling systems of nonhuman primates that function on a motivational as opposed to a symbolic level. Subsequently, an empathy model that implicates both motivational and cognitive factors in responsiveness to the cry is presented.

The Cry as a Graded Signal

In the light of the previous discussions of the physical characteristics of the cry, infant crying can be likened to biologically significant sounds that are graded signals as opposed to discrete signals (Wilson, 1975). Discrete signals operate in an on–off manner with no variation in intensity or duration, whereas graded signals are variable and increase in intensity with the greater motivation of the signaler. In nonhuman primates, discrete signals are found among tree-dwelling primates, and graded signals are common among terrestrial species (Wordon & Galambos, 1972). Discrete signals are adapted to communicating territorial messages over large distances in noisy environments; graded signals are adapted to communication within the troop at relatively close ranges. Graded signals cannot be easily characterized acoustically and are hard to dissect into specific messages. Unlike in human language, these graded signals reflect the motivational state of the signaler rather than state a relationship in symbolic terms (Brown, 1975). The meaning of a graded signal depends on both acoustic cues and nonacoustic cues such as the context in which the signal is employed. However, it is possible that dramatic shifts in the intensity of graded signals may result in shifts in qualitative meaning (Wilson, 1975).

This description of graded signals fits well with the discussion presented earlier concerning the signal value of the cry. It was proposed that cries differ in intensity and that intensity cues may result in listeners' making qualitative distinctions about the underlying causes of cries. In addition, the importance of context in interpreting the meaning of the cry has been emphasized by some researchers (Bernal, 1972; Muller et al., 1974; Wolff, 1969). A cry that occurs immediately after a feed is less likely to be interpreted as a hunger cry than a cry that occurs 2 hours or more after a feed. Thus, both intensity cues and context enter into the interpretation of the cry signal.

There is comparative evidence that supports the conceptualization of the infant cry (as well as some adult sounds such as laughter and moaning) as similar to graded primate signaling systems. These human utterances, which could be described broadly as expletives, are produced with a comparable simplicity and steadiness of upper vocal tract configuration and with predominant variations in the lower vocal tract (Bastian, 1965). According to Bastian, the lower vocal tract controls pitch, timing, and intensity and is closely tied to the autonomic system of arousal. In fact, the anatomical configuration of the infant vocal tract is said to be more similar to that of a nonhuman primate than to that of an adult human (Lieberman, Harris, Wolff, & Russell, 1972). The infant, like the nonhuman primate, does not have a pharyngeal region that can vary in cross-sectional area. Lieberman (1973), noting the similarity in the vocal tracts of infants, adult chimpanzees, and the prehistoric ancestors of *Homo sapiens,* placed great emphasis upon the evolution of the anatomy of the vocal tract as an important factor in the evolutionary development of human language.

That the emission of the infant cry is postulated to be under the control of the hypothalamic and the interrelated limbic system (Chauchard, 1963; Torda, 1976) also reinforces its similarity with nonhuman primate auditory signaling systems. Robinson (1967) has demonstrated that every type of vocalization common to macaques can be elicited by stimulating parts of the limbic system. In fact, removal of areas of the nonhuman primate brain that are homologous to the speech centers in human beings does not affect their vocalization (Myers, 1968). Both the facial and vocal expressions of these monkeys seem not to be under voluntary control, but are primarily controlled by portions of the brain subserving emotional rather than volitional functions. Myer further hypothesized that, based on lesion studies with humans, there is a striking duality in the mode of social communication and its underlying mechanisms in humans. The involuntary expression of affect (facial expressions and vocalizations) appears to be controlled, as in nonhuman primates, by the deep structures constituting the limbic system, whereas the voluntary uses of these expressions are under cortical control.

Thus, in this framework, the cry of the newborn is characterized as an involuntary reflex action to distress that is at first under the control of the hypothalamic/limbic system and only later comes under cortical control. Bell and Ainsworth's (1972) hypothesis that crying is at first reflexive and only later becomes instrumental may reflect increasing cortical control over the emission of the cry in the second half of the first year. Also in this formulation, the cry is regarded as a graded rather than a discrete signal that increases in intensity with the degree of discomfort felt by the infant. Any attempt to interpret the cause of the distress would make use of both acoustic cues of intensity (e.g., dysphonation, hyperphonation, and prolongation of the signal) and contextual factors. This suggests that the meaning of the cry for the listener could be fruitfully studied using a dimensional approach as opposed to the typological approach adopted in the past to study the signal value of cries.

If the infant cry is a graded signal, then the manner of its reception by adults may likewise bear some similarity to the reception of graded signals by nonhuman primates. Effective reception of graded signals is predicated on a modification of the emotional disposition of the listener (Bastian, 1965). Thus, communication with graded signals, both their emission and their reception, can be said to be more on a motivational or emotional basis than on a symbolic one (Brown, 1975). Graded signals do not convey impartial messages but have their effect by influencing the motivational state of the listener.

The emission of the cry as well as its compelling effect on the listener may, then, be under the control of the limbic/hypothalamic system and its modulation of autonomic arousal. In spite of the prominence of cortical control in humans, it is also believed that a considerable role is played by the limbic/hypothalamic system in the reception and execution of elementary types of affective speech and sound making (Chauchard, 1963). Similarly, the triune concept of the brain proposed by McClean (1973) emphasizes the intermeshing of cortical with subcortical functions. The oldest part of the brain comprising the upper brain stem is our inheritance from reptiles and controls functions like respiration and perhaps also stereotyped behavior patterns such as those released by sign stimuli. At the next level, the old mammalian brain includes the hypothalamic/limbic system and controls species-typical behavior such as agonistic, affiliative, and parental behaviors (Altmann, 1966). McClean (1973) presented evidence that the old mammalian brain consists of functional areas that guide behavior with respect to the two life principles—self-preservation and preservation of the species. The old mammalian brain in humans has a similar structure to that found in animals and, he argues, continues to function at an animalistic level in humans with its contribution to the elaboration of emotional feelings that guide behavior. At the highest level, the new mammalian brain or neocortex functions in skilled, discriminatory, and exploratory behaviors.

McClean (1973) hypothesized that the interconnections of the limbic system and the neocortex represent an evolutionary advance in primates that makes possible empathy in terms of both shared affect and a cognitive understanding of another's feelings. The compelling effect of the cry on the listener may be partly due to the fact that it produces an isomorphic response of distress in the listener that is mediated by the limbic system. Before discussing the altruistic basis for responses to the cry, I first examine claims that the motivation to respond to the cry is solely egoistic or self-serving.

The Egoistic Basis for Response to the Cry

In arguments advanced against the releaser model, researchers in the learning tradition (Moss & Robson, Note 2) have suggested that parents respond to the cries of their infants for the same reason that they respond to any noxious sound, that is, to reduce aversive stimulation. This view rests on principles of negative reinforcement as well as on psychophysical assumptions of the relationship between the quality of the auditory experience and the physical characteristics of the sound. Whereas the releaser model emphasizes the uniqueness of a particular stimulus and its receptor mechanisms,

the psychophysical approach stresses general properties of the auditory processing system.

Although no formal psychophysical study has been conducted with the cry sound, Ostwald (1963, 1972, 1973) has presented many speculations as to what physical characteristics of the sound would make it a particularly penetrating noise. He compared the cry to a siren that compresses acoustical energy into a very sensitive region of the auditory spectrum. He reported that the fundamental frequency of most cries is approximately 500 Hz (ranging from 400 to 600 Hz) with heaviest reinforcement at 1000 to 2000 Hz, where the auditory threshold is lowest. In addition, he claimed that the infant cry is one of the loudest sounds human beings ever make, with an average level of 83 to 85 dB at 10 inches (2.54 cm) from the mouth. According to Ostwald, this sound level is 20 dB louder than normal adult speech and is equivalent to the noise of an unmuffled truck. Ostwald's (1963) conceptualization of the basis for parental response to the cry is similar to that advanced by learning theorists:

> One can appreciate why the parent must interfere with the baby's cry: this sound is too annoying to be tolerated beyond a short period of time, particularly at close range. Thus, the cry cries to be turned off! The listener who cannot escape usually reduces the noise by soothing whatever baby needs occasion it. (p. 46)

Psychoacousticians (Kryter, 1970) have claimed, however, that research on the annoyance value of sounds has little application to sounds that convey emotional meanings. The effects of sounds such as the cry that carry information about their sources cannot be quantitatively related to their physical characteristics and are therefore rejected from the concept of perceived noisiness. However, some basic attributes related to perceived noisiness, such as impulsiveness and spectrum content and level, may set fundamental limits on the tolerability of the noise, but emotional meaning can greatly alter tolerance within these limits.

Although the psychophysical approach to the explanation of the perceptual mechanisms underlying the impact of the cry may have some validity, the greatest weakness in this approach is that it accounts best for escape from or avoidance of the crying child and less well for approaches to remove the source of distress. The motivation is egoistic or self-serving in that the parent is motivated to reduce his or her own distress rather than the baby's. Hoffman's (1975) theory of empathic distress as the basis for altruism provides an alternative view of the motivation to respond to the cry.

The Altruistic Basis for Response to the Cry

Many conceptions of empathy have emphasized either the affective aspect of sharing the feelings of others or the cognitive awareness (recognition) of another's plight (Deutsch & Madle, 1975), whereas Hoffman (1975) has presented a formulation that synthesizes the cognitive and affective components in a developmental perspective. At the basis of all altruism is the response of empathic distress or "the involuntary, forceful experiencing of another person's painful emotional state" (p. 613). The experience of empathic distress is necessarily discomforting and unpleasant. As mentioned earlier, on the basis of Simner's (1971) research, Hoffman proposed that empathic distress may exist in a rudimentary form at birth or may come about through classical conditioning.

Integrating the research on cognitive development and on helping behavior, Hoffman proposed three stages in the development of altruistic motivation. Adopting Schacter and Singer's (1962) formulation that the labeling of one's emotion or state of arousal is determined by one's cognitions of the situation, Hoffman suggested that one's cognitive sense of the other likewise determines how one reacts to the distress response of another. Through the development of a cognitive sense of the other, the primitive empathic distress response develops in three stages into a more reciprocal concern for the victim, which Hoffman called sympathetic distress. At first the child is unable to differentiate between his or her own distress and that of another. With the development of the concept of the self as distinct from others, the child's concern for his or her own discomfort is transformed into concern for the other's distress,

but he or she lacks understanding of the cause or remedy of another's distress. At the next stage, the child's attempt to alleviate another's distress is less egocentric and is guided by corrective feedback from immediate situational cues. At the third and highest level, the child can respond not only to situation-specific cues of distress but also to a general representation of the welfare of the victim regardless of the victim's momentary state.

Hoffman further presented some evidence to support the following relationships between altruistic motives and action: (a) Distress cues from another trigger the sympathetic distress response in the observer; (b) the observer's initial tendency is to act; (c) the intensity of the affect and the speed of response should increase with the number of pain cues; (d) if the observer does not act, the observer will continue to experience sympathetic distress or cognitively restructure the situation to justify inaction.

It is instructive to relate Hoffman's formulation to infant crying. First, that the cry is often described as a noxious stimulus accords with the experience of empathic distress as unpleasant. Second, the description of the cry as a compelling stimulus reflects the compulsion to act by observers of another's distress. Third, that the speed of response is increased by the salience of the pain cues has been borne out by Wolff's (1969) data on latency of maternal response to hunger and pain cries. That the intensity of affect should increase with the intensity of pain cues would also be consistent with the concept of the cry as a graded signal.

If, as Hoffman proposed, failure to act results in the observer cognitively restructuring the situation to justify inaction, we may have a clue as to how failures to act and even vengeful acts in response to the cry could come about. At Hoffman's third level of development of altruistic motivation, the observer's representation of the general welfare of the distressed person may override the specific situational cues associated with distress. Thus, if one's child-rearing philosophy is that one should not accede to the infant's distress signals, one might justify inaction under the rubric of teaching the child that he or she must not manipulate the parent. Similarly, conceptions of the relative vulnerability of infants at various ages may lead parents to be less responsive to the distress signals of older infants than to those of younger infants. If, despite this cognitive restructuring, the parents continue to experience involuntary distress, they may try to escape by increasing the distance between themselves and the crying child or, for example, by closing doors to dampen the sound. It may be that continued exposure to the sounds with the attendant involuntary experiencing of a high level of emotional arousal in the parent tips the parent's motivation from altruistic to egoistic, that is, the motivation is no longer to alleviate the infant's distress but to alleviate the parent's distress at having to listen to the sound of crying for prolonged periods of time. This contrasts with the altruistic basis for helping behavior in which the motivation to respond is aroused by another's distress rather than by one's own, in which the major goal is to help the other rather than one's self, and in which gratification is contingent on reducing another's rather than one's own distress (Hoffman, 1975).

The notion that there may be an optimal range of distress cues has been hypothesized by Hoffman (Note 3) and has been referred to as the "critical toxicity" problem by Tompkins (1963) in his discussion of emotions aroused in listeners by infant cries. Distress cues from another must be sufficient to activate distress in the observer but must not be so disturbing as to elicit avoidance of or aggression toward the victim. Excessive and prolonged crying, whether due to constitutional factors in the infant or parental management techniques, may exceed limits of tolerability and overly tax parents' abilities to withstand continuing high levels of emotional arousal.

The model of the cry as an activator of altruistic or egoistic motives in the listener may shed some light on ideologies and actions in our culture with regard to the socialization of crying in infancy. Tompkins (1963) argued on the basis of clinical observation that most people develop articulate philosophies about crying and that, generally speak-

ing, there is a polarization of attitudes such that one is either for or against the crying child. These differing attitudes lead to a polarization of action as well: Either one ignores and thereby punishes the crying child or one tries to soothe the child by removing the source of the distress. In the latter case the parent is motivated to action because he or she experiences sympathetic distress. In the former case, however, the cry is seen as an attempt on the part of the infant to manipulate the parent. The response of the parent is characterized by irritation, anger, and annoyance. By ignoring the cry, these parents hope to reduce the child's dependency and increase his or her self-reliance.

The belief described by Tompkins that babies could be spoiled by responses to their cries was prevalent in child-care advice given to American parents in the first half of this century (Bell & Ainsworth, 1972). To the contrary, Bell and Ainsworth have presented evidence that by not responding promptly to the cries of infants in the first 6 months, parents actually increase the likelihood that their infants will cry more frequently and for longer periods of time in the second half of the first year. By this time, a vicious spiral has been set up whereby more crying leads to more ignoring and more ignoring leads to more crying. In the context of the empathy model proposed, these findings together with Tompkins' observations suggest that one's ideology or cognitive representation of the crying infant's well-being may lead to a caregiving pattern that routinely exposes parents to excessive crying. Frequent exposure to excessive crying would be expected to activate parents' egoistic motives and result in anger toward and avoidance of the source of the sound, thereby completing and escalating the vicious spiral. Reports that abusing parents hold extreme views about spoiling and independence training (Steele & Pollock, 1968) also suggest that their management techniques may foster the excessive crying often given as the reason for abuse.

However, the question can be reversed, and one can ask instead whether prolonged crying may foster the punitive ideology as well as the behavioral unresponsiveness. Bell (1968, 1971) argued that much of the research based on the parent-effect model can be reinterpreted as demonstrating the effects of the child's behavior on the parent. Indeed, recent reports (Lamb, Note 4) suggest that babies who are abused may be especially difficult constitutionally and may therefore precipitate their own abuse. In this regard, it is interesting to consider Bennett's (1971) report that nurses may apply either the altruistic or the punitive ideology described by Tompkins depending on the characteristics of the particular babies in their care. The cries of one very irritable and difficult newborn were viewed as exploitive by nurses, whereas those of an easier baby elicited sympathy and were regarded as legitimate demands. Although both babies were easily soothed by the nurses' interventions, quieting was seen as due to the infant's being "spoiled" in the one case and "socially responsive" in the other. During the first two weeks after delivery, the frequent cries of the spoiled baby were often left unattended, but those of the socially responsive baby were always attended to promptly.

Although extremes of irritability may be the cause of caregiver unresponsiveness in individual cases, the wide variations between cultures in amounts of crying (Konner, 1972; Mead & Newton, 1967) suggest the importance of other factors. Prompt responding to the cry in cultures with a developed transition period in which breast-feeding is the norm may be partly mediated by the effect of the milk letdown reflex on the mother (Mead & Newton, 1967). Greater intimacy of contact (Konner, 1972) in these cultures also provides the opportunity for caregivers to anticipate the needs of babies by interpreting more subtle proximal signals of discomfort. In addition, the ecological setting of many primitive and traditional cultures ensures the availability of many caregivers (Marvin, Van Devender, Iwanaga, LeVine, & LeVine, 1977). Where several caregivers in addition to the mother are concurrently available, prompt attention to distress cues is more feasible than in the typically Western nuclear-family setting with its competing demands on parents. With respect to more cognitive factors, one might hypothesize that in primitive and traditional cultures concep-

tions of the vulnerability of infants are greater than in industrial nations in which infant mortality rates are lower. Cross-cultural variations in responsiveness may be influenced by differing conceptions of the well-being of distressed infants and may result in greater or lesser attention to specific situational cues of distress. That caregivers in a primitive culture interpret the slightest cry as an emergency signal (Devore & Konner, 1974) is consistent with this hypothesis.

The precise interrelationships among empathic distress, parental behavior, motives, ideologies, and infant outcomes require further exploration. In reviewing the available empirical evidence, Hoffman's empathy model has provided useful hypotheses. Future research within this theoretical framework promises to further our understanding of both the compelling effect of the cry and the nature of the outcome for the distressed infant. In addition, it may be useful to supplement this framework with a consideration of the role of nature and nurture in the ontogeny of parental behavior. Given that from an evolutionary perspective parental behavior is not strictly altruistic because it contributes to the parent's reproductive success (Alexander, 1974), one might expect that there are additional mechanisms underlying the display of parental behavior in general and responsiveness to crying in particular. In the next brief section, the role of exposure to infants in the ontogeny of parental behavior is discussed with reference to possible physiological factors that may predispose women to find infantile cues more attractive than men find them.

Factors That Influence the Ontogeny of Parental Behavior

Because care of the young is crucial for genome survival, the question explored in this section is whether there may be mechanisms that foster empathic responsiveness toward infants in particular in addition to the processes outlined by Hoffman (1975) that contribute to a general capacity for empathy. A variety of mechanisms can be accommodated within the framework of Hoffman's model because the theory does not preclude the involvement of constitutional as well as experiential factors in the development of empathy. The interactionist approach to the study of development in behavioral biology also allows for multiple causative factors and has been found useful in organizing the presentation to follow. In this framework, species-typical behavior is seen as developing toward a predictable end product regardless of whether experiential or constitutional factors are involved in its development (Lehrman, 1970; Wilson, 1975).

Although evidence has been cited that women are generally more empathic than men when affective indices are used (Hoffman & Levine, 1976), the question addressed here is whether altruistic behavior toward the young in particular may be facilitated by hormonal action in women. Several findings in the human literature are consistent with the comparative literature in suggesting that hormonal events during the prenatal period and at parturition may enhance the attractiveness of infantile stimulation for women. In humans, there may be further effects of hormonal changes at puberty on the attractiveness of infantile cues for women.

The inductive or irreversible influences of circulating hormones on the sexual differentiation of mammalian fetuses have been documented for the human species as well as for animals (Money & Erhardt, 1972). Regardless of the genetic sex of the fetus, exposure to male sex hormones (androgens) at a critical period results in development according to the masculine anatomical pattern. That these hormonal influences are not merely anatomical is suggested by the research of Money and Erhardt (1972); in a study of fetally androgenized girls, they found that as preadolescents these girls exhibited tomboyish behaviors. When compared with normal girls of their age, the fetally androgenized girls preferred active sports to passive activities such as doll play; they preferred boys to girls as playmates; they preferred to wear functional clothing, for example, slacks rather than dresses; and they were more career- than marriage-oriented in their expectations for their futures. These findings were subsequently replicated with a different sample (Erhardt & Baker, 1974). Money and Er-

hardt speculated that prenatal hormonal exposure to androgens may act to raise the threshold of sensitivity to stimuli associated with the traditional nurturant caregiving role.

Possible influences of hormonal changes at puberty on the attractiveness of infantile cues are suggested by two studies. Fullard and Reiling (1976), in a developmental investigation of Lorenz's "babyness," found that children from about the age of 8 until the age of 12 preferred pictures of adults to pictures of infants. However, between the ages of 12 and 14, the preference of females shifted to infants. Males' preferences for infants did not significantly exceed chance level until adulthood (older than 18 years). Similarly, Huckstedt (1965) found that females preferred a drawing of a supernormal baby (with exaggerated infantile features) to that of a normal baby at 10 to 13 years of age but that this preference was not reliable for males until 18 to 21 years of age.

These findings suggest that prenatal hormonal events and hormonal changes at puberty may operate to bias females toward the eventual adoption of the caregiving role. However, it is difficult to rule out the effects of socialization pressures, as Quadnago and his colleagues (Quadnago, Briscoe, & Quadnago, 1977) have pointed out, or the effects of differential exposure to infants that females may gain prior to adulthood as a result of societal pressures.

Hormonal changes associated with pregnancy and parturition have been held responsible for the induction or rapid onset of caregiving behavior in some mammals, as for example in goats (Klopfer, 1971), in hamsters (Richards, 1966), and in the laboratory rat (Moltz, 1974; Rosenblatt, 1970). These hormonal changes appear to sensitize the mother to cues emanating from the young. Similarly, it has been argued that the hormonal changes surrounding parturition may produce a critical period for the establishment of caregiving in human mothers as well. Salk (1970), for example, found that prolonged separation (1 to 7 days beginning at birth) of mothers from their premature and full-term infants resulted in deviations from the normal pattern of holding infants on the left side (regardless of the handedness of mothers). Klaus and Kennell (1970) also found persistent differences in caregiving behavior between mothers who were allowed early contact with their premature babies and mothers who were only allowed late contact. In more recent studies Klaus has extended his studies to mothers of full-term infants allowed extended or traditional contact with their babies in the first 3 days after delivery. Several findings particularly relevant to responsiveness to infant crying were reported. One month after hospital discharge, mothers in the extended-contact group reported in an interview that they picked up their babies when they cried more often than did mothers in the traditional-contact group (Klaus et al., 1972). Extended-contact mothers were also observed to soothe their infants more often during a physical examination 1 month after hospital discharge (Kennell et al., 1974). The effects of extended contact on responsiveness to crying continued to be evident during a follow-up 11 months later. The mothers in the extended-contact group spent more time soothing their infants when they cried during a physical examination at 1 year of age (Kennell et al., 1974). Klaus and his colleagues argued that early separation affects the mother's commitment and attachment to her infant, her development of a sense of caregiving abilities, and her ability to establish an efficient caregiving regimen (Barnett, Leiderman, Grobstein, & Klaus, 1970). Klaus's findings may have important implications for epidemiological studies of child abuse, as early mother–infant separation along with other adverse factors is reportedly more common among abused children than among unabused siblings (Lynch, 1975).

Whereas hormonal induction in the female rat may be necessary at the outset for the rapid *initiation* of caregiving behavior, *maintenance* of caregiving is less dependent on hormones than on stimulation emanating from the young (Moltz, 1974; Rosenblatt, 1970). The hormonal conditions associated with lactation are not necessary to maintain caregiving behavior, but there is evidence that the presence of prolactin in lactating rats may play a facilitative role by reducing the mother's physiological and behavioral responsiveness to stress (Thoman, Conner, &

Levine, 1970). The influence of prolactin on the behavior of human mothers is not known. It is interesting to note, however, that in one study (Bernal, 1972), breast-feeding mothers responded to crying more quickly than did bottle-feeding mothers and were more likely to respond with feeding. Prompt responding to cries by the breast-feeding mother may be mediated by the effect of the cry on the letdown reflex, as suggested by Mead and Newton (1967), and/or by the effect of the cry on changes in the temperature of the lactating breast (Vuorenkoski, Wasz-Hockert, Kiovisto, & Lind, 1969). Alternatively, if prolactin makes human as well as rodent mothers less prone to stress, the threshold of breast-feeding mothers for the activation of egoistic motives may be higher than that of bottle-feeding mothers.

Turning now to the nonhormonal bases for caregiving behavior, the role of exposure to the young has been emphasized in reviews of the ontogeny of caregiving behavior in mammals (Moltz, 1971; Noirot, 1972; Rosenblatt, 1970). For example, enforced exposure to the young elicits appropriate caregiving such as nest building and retrieving in virgin female and male rats. The length of time required to induce caregiving behavior by exposure to pups (about 6 days), however, far exceeds limits that would be adaptive in the natural context, as pups would die without appropriate care for that period of time. It has been concluded from these studies that caregiving behavior is characteristic of both sexes in the species studied. Caregiving is not dependent on physiological changes for its appearance, but the hormonal changes associated with parturition in the female reduce the duration of exposure to the young that is required to effect a change from attacking or avoidance to caregiving behavior. The effects of the mother's parity on caregiving behavior provide further evidence of the effects of exposure to the young. When the natural sequence of hormonal changes at parturition is disrupted, multiparous rats provide adequate care, whereas 50% of primiparous rats do not (Moltz, 1971). Thus, prior exposure to pup stimuli can compensate for disruptions in mechanisms under hormonal control.

Harper (1971) has reviewed studies that suggest that exposure to the young may sensitize higher as well as lower mammals to care-eliciting cues. A dramatic example of this phenomenon was reported by Harlow and his colleagues (Harlow, Harlow, Dodsworth, & Arling, 1966). Although their isolation-reared rhesus mothers were extremely abusive with their first infants, they performed adequately as mothers with their second infants despite the traumatic nature of their earlier experiences. Salk (1970) also noted the compensatory effects of parity for human mothers. He found that the effect of mother–infant separation on which side of the body the infant was held by the mother was overridden if the mother had previously had a child from which she was not separated in the early postpartum period. That past experience in rearing infants influences the attraction of adult rhesus females to neonates was reported by Sackett (1970). Using a "self-selection circus" that allowed the tested animal to approach other animals of varying ages and sexes, he found that multiparous females spent the most time with neonates, followed by primiparous females who, in turn, spent more time with neonates than did nulliparous females.

The parity of human mothers has also been associated with responsiveness to crying in a study by Bernal (1972). Mothers of second borns were less likely to ignore crying and were more likely to respond promptly than were mothers of firstborns. It is possible that exposure to infants increases the tolerability of the sound of crying for parents and reduces the likelihood of avoidance responses. One could also argue that increased responsiveness to second borns resulted from altered conceptions of the needs of infants in the newborn period. However, a cognitive interpretation of these results seems less likely in the light of Bernal's finding that the behavior of multiparas contradicted their intentions as stated in prenatal interviews. Although 85% of multiparas intended to respond to crying only after 10 minutes, 70% of them actually responded to crying within 10 minutes (for primiparas these percentages were 50% and 62%, respectively). Evidence that contingent responsiveness increases with

parity is, however, equivocal. Another study (Cohen & Beckwith, 1977) found a reduction in contingent responsiveness with parity, which the investigators attributed to the competing demands of the older sibling. A study in which the spacing between infants and their older siblings is controlled may resolve the apparent discrepancy in reported relationships between parity and responsiveness to crying.

In summary, the studies reviewed suggest that a major factor in the ontogeny of mammalian parental behavior is exposure to the young and its enhancement of the attractiveness of the young for adult male and female species members. Females, however, may have somewhat of an advantage over males in terms of hormonal mechanisms that sensitize them to infantile cues. The net effect of the interaction of organismic and experiential factors may account for the greater participation of females in infant care among humans as well as among lower mammals. Nevertheless, among human populations, observed sex differences would be expected to vary across cultures depending on the opportunities provided within each culture for males to be exposed to the eliciting effect of infantile stimulation. The lesser sensitivity to crying in Western than in primitive and traditional cultures may partly be a function of a rearing pattern that not only reduces the intimacy of contact between parents and infants in general but also traditionally prohibits extended contact early in the postpartum period when the mother's sensitivity to care-eliciting cues may be greatest. In addition, increases in the attractiveness of infants for pubertal girls may indicate a heightened susceptibility to observational learning in the prereproductive period for which opportunities are often lacking in Western cultures in which infant care usually takes place in the privacy of the small nuclear-family home. Altruistic behavior toward crying infants must then be viewed in the specific context of ontogenetic processes that sensitize adults to infantile cues and enhance the attractiveness of the young for them.

Summary

This article began with the common observation that the infant cry is a compelling sound that elicits actions of either a nurturant or a nonnurturant (even homicidal) nature from adults. Two models of the mechanisms by which the cry has its powerful impact were examined.

The first model examined was that of the cry as a releaser of parental behavior. In this theoretical framework, the cry is viewed as a distress signal that originally evolved, along with other attachment behaviors, to promote proximity between infants and their caregivers. Close proximity between caregiver and infant functioned to protect the infant from predators in the dangerous environment in which the species evolved. To ensure genome survival, reciprocal mechanisms evolved in caregivers to promote immediate and appropriate responses to the cry signal. In this context, it has been hypothesized that the cry may act as a releaser—a key stimulus that acts figuratively to release a fixed motor response from the receiver. The recognition of the signal and the production of the motor response are said to be under the control of a hypothesized neural filtering system referred to as an innate releasing mechanism. The model of the cry as a releaser was examined in the light of the available literature on the physical characteristics of the infant cry and its effectiveness in eliciting parental behavior. It was found that the key features of the cry stimulus that have been identified relate more to stimulus intensity than to stimulus recognition. In addition, the cry was not found to be invariably effective in eliciting caregiving behavior, particularly in Western cultures. This analysis suggested that the data available, though not entirely compatible with the classical view of IRMs, may be compatible with the broadened definition of releasers as motivational entities adopted by some modern ethologists.

A model of the cry as an activator of emotions was then examined. In this formulation, the cry is likened to the graded signals employed for communication by some nonhuman primates. The cry is viewed as an involuntary reflex action to distress that in-

creases in intensity with the greater motivation or discomfort felt by the infant. The response to the cry likewise consists of an isomorphic response of distress in the observer. Egoistic or self-serving motives for responses to the cry, that is, to reduce the parent's own distress, may account for attempts to avoid or escape from the crying infant. On the other hand, altruistic motives, that is, to reduce the baby's distress, may underlie parental responses aimed at removing the source of the infant's discomfort.

Within the framework of Hoffman's empathy model (1975), altruistic behavior toward persons in distress is viewed as a joint product of the capacity for shared affect and the development of a reciprocal concern for others. Although the triggering of empathic distress usually results in the performance of an altruistic act, exposure to excessive crying may transform the parent's motivation from altruistic to egoistic, that is, to a concern to alleviate the parent's own distress rather than the infant's. The roles of constitutional irritability in the infant as well as parental child-rearing philosophies and management techniques were discussed in relation to the activation of egoistic motives and behavior toward crying infants. Egoistic motives may occur more frequently in Western than in primitive and traditional cultures because of a child-rearing pattern that promotes excessive crying and thereby overly taxes parents' abilities to withstand continuing high levels of emotional arousal.

Because caregiving behavior is important for genome survival, it was argued that the explanatory power of the general empathy model proposed could be further increased by taking into consideration specific ontogenetic processes that foster altruistic behavior toward infants in mammals. A review of the human and comparative literature suggested that the ontogeny of mammalian parental behavior may be under the control of two separate but interacting mechanisms. Whereas hormonal events sensitize female species members to infantile cues, exposure to the young has comparable effects for males and females. Sensitization, whether due to hormonal or to experiential factors, enhances the attractiveness of the young for adult species members. Altruistic behavior toward crying infants must be viewed within the context of these ontogenetic processes that have evolved to ensure genome survival.

Psychological Bulletin

(Continued on inside back cover)

BLISHED BIMONTHLY BY THE AMERICAN PSYCHOLOGICAL ASSOCIATION
ISSN 0033-2909

The *Psychological Bulletin* publishes evaluative reviews and interpretations of substantive and methodological issues in the psychological research literature. The Journal reports original research only when it illustrates some methodological problem or issue. Discussions of methodological issues should be aimed at the solution of some particular research problem on psychology, but should be of sufficient breadth to interest a wide readership among psychologists; articles of a more specialized nature can be directed to the various statistical, psychometric, and methodological journals. The *Bulletin* does not publish original theoretical articles; these should be submitted to the *Psychological Review*.

Abstracts: All articles must be preceded by an abstract of 100–175 words. Detailed instructions for preparation of abstracts appear in the *Publication Manual of the American Psychological Association* (2nd ed.), or they may be obtained from the Editor or from APA Central Office.

Blind review: Because reviewers have agreed to participate in a blind reviewing system, authors submitting manuscripts are requested to include with each copy of the manuscript a cover sheet, which shows the title of the manuscript, the name of the author or authors, the author's institutional affiliation, and the date the manuscript is submitted. The first page of the manuscript should omit the author's name and affiliation but should include the title of the manuscript and the date it is submitted. Footnotes containing information pertaining to the author's identity or affiliation should be on separate pages. Every effort should be made to see that the manuscript itself contains no clues to the author's identity.

Manuscripts: Submit manuscripts in triplicate to the Editor, R. J. Herrnstein, *Psychological Bulletin,* Harvard University, 33 Kirkland Street, Cambridge, Massachusetts 02138, according to instructions provided below.

Instructions to Authors: Authors should follow the directions given in the *Publication Manual of the American Psychological Association* (2nd ed.). Instructions on tables, figures, references, metrics, and typing (all copy must be double-spaced) appear in the Manual. Authors are requested to refer to the "Guidelines for Nonsexist Language in APA Journals" (Publication Manual Change Sheet 2, *American Psychologist,* June 1977, pp. 487–494) before submitting manuscripts to this journal. All manuscripts should be submitted in duplicate and both copies should be clear, readable, and on paper of good quality. Dittoed copies are not acceptable and will not be considered. Authors are cautioned to carefully check the typing of the final copy and to retain a copy of the manuscript to guard against loss in the mail.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1979: $40 domestic, $42 foreign, $7 single issue. APA member rate: $15. Write to Subscription Section, APA.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Dept., APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Published bimonthly (beginning in January) in one volume per year by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Arlington, Va., and at additional mailing offices.

Statistical Analysis of Dyadic Social Behavior

Helena Chmura Kraemer
Department of Psychiatry and Behavioral Sciences
Stanford University Medical Center

Carol Nagy Jacklin
Stanford University

A method is described for determining the effects of sex (or any other dichotomous characteristic) from the individual correlated behavioral responses observed in dyadic interactional situations. In the illustration used, the dyads are of three types: girl–girl, girl–boy, and boy–boy. Main effects of sex of subject and of sex of partner and interaction effects are estimated and tested, using a generalization of the matched-pair *t*-test approach. Intragroup correlations between paired responses are examined separately. Alternative procedures of analysis are discussed and compared. The present method is extended to interacting groups larger than dyads when the subject characteristic remains dichotomous (e.g., boys and girls in groups of three, four, etc.). In these cases there are three intragroup correlations of interest for responses within the same interacting groups: boys versus boys, boys versus girls, and girls versus girls.

The person with whom one interacts influences what one does. This interdependency of behavior has psychological, as well as statistical, implications. Unfortunately, researchers have either ignored the interdependency or tried to eliminate it, since certain statistical procedures do not allow for it.

To eliminate the dependency, several approaches can be taken. For example, studies with adults often use confederates to provide a standard against which subjects' behavior can be measured. Not only is this strategy difficult to implement in studies of children but it is also not always clear that results obtained using confederates generalize to groups, all of whose members are naive. Alternatively, the dependency of partners' scores can be eliminated by devising scores that apply only to a group or an interacting pair. These scores are dyadic in nature, that is, they can only be attributed to the dyad and not to the individuals within the dyad (e.g., eye-to-eye contact or tug-of-war scores). With scores that can be given to each individual in the dyad separately, one can avoid the issue of dependency by summing individual scores across partners and using only this pair score. In all three cases—using confederates, using scores dyadic in nature, or using pair-average scores—the statistical problems created by dependency are avoided.

Although some questions can be appropriately answered by such scores, there are

This research was partially supported by National Institute of Mental Health Grant HD-9814-02. The authors wish to thank Sandra Lipsitz Bem, Anne Petersen, and John Martin for their careful reading of the manuscript.

Requests for reprints should be sent to Helena C. Kraemer, Department of Psychiatry and Behavioral Sciences, Stanford University Medical Center, Stanford, California 94305.

many important kinds of questions that cannot be answered without individual measures for both members of a dyad (or an interactive group). First, the nature of the mutual dependency of subject and partner behaviors itself varies across groups (Jacklin & Maccoby, 1978), and this fact is of course lost in studies with confererates or with pair or dyad scores. Second, effects of the partner as stimulus may be lost. For example, children have been shown to behave differently in the presence of a boy as opposed to a girl. In the presence of a girl, both boys and girls are more likely to offer toys and behave in other positive ways. However, in the presence of a boy, both boys and girls are more likely to withdraw (see Jacklin & Maccoby, 1978). Use of a score for each pair would only allow overall comparisons of boy–boy, girl–girl and mixed–sex pairs and would mask these sex-of-partner effects.

Thus, a variety of questions can be asked about dyadic effects, the answers to which depend on observations of each member of a dyad (or more generally, on observations of each member of an interactive group). The examples given here are questions about sex differences in children. Isolating the contributions of sex of subject, sex of partner, and the interaction of these two from one another has been found necessary to an understanding of children's social behavior (see Jacklin & Maccoby, 1978). However, the same problem exists for any characteristic of the subject or partner that is being investigated.

Several studies have looked at the nature of interpersonal behavior in young children when some characteristic of the subjects or partners is of interest. Statistical approaches to the dependency problem have varied. Muste and Sharpe (1947), for example, avoided the issue by presenting only descriptive material. A number of researchers have used pair scores (Eckerman, Whatley, & Kutz, 1975; Nadelman & Schiffler, Note 1; Ross & Hay, Note 2). Others seem to have assumed (considering the statistical tests that they used) that partners' behaviors are not interrelated (Doyle, 1975; Hartup, 1974; Langlois, Gottfried, & Seay, 1973; Roff & Roff, 1940; Langlois & Downs, Note 3). The statistical procedures commonly used to evaluate data of this type depend for their validity on adherence to the assumption that the individual scores are independent. However, it is clear that when the behaviors of subjects and their partners are put into the same analysis, this assumption of independence is often violated. As an example, let us consider an extreme case. Suppose that a child's behavior exactly matches that of his or her playmate in some respect. Putting the two members of a pair into an analysis as though they were independent would be equivalent to putting the same case in twice, thus doubling the permissible degrees of freedom and underestimating the error variance. In the more usual case, mutual dependence of behaviors is only partial, but to the extent that mutuality does exist, the inappropriateness of the usual statistical treatments becomes a serious problem. If one wished, for example, to compare the behavior of a girl when she plays with another girl with the behavior of a girl when she plays with a boy, there would be a potentially serious violation of assumptions if both members of each pair were treated as subjects and put into any analysis that disregarded the mutual dependence of behaviors.

This problem is well-known in other contexts. If, for example, one assigns one member of a matched pair to one group and the other to a comparison group, comparison of group response must be based on the matched-pairs t test or the Wilcoxon signed-ranks test rather than on the usual Student's t test or the Mann-Whitney U test, which require independent responses. If one assesses the effect of k different treatments, with each subject exposed to each treatment, analysis of treatment effect must be based on a repeated measures analysis of variance (ANOVA) or a Friedman test rather than one an ANOVA of a one-way layout or a Kruskal-Wallis H test, both of which, again, assume independence of observations. However, in studies of social behavior, the possible dependency has not always been taken into account.

In summary, we suggest that interpersonal behavior often involves the interdependency of subject's and partner's behaviors. Generally, researchers have avoided the statistical problems inherent in this interdependency by using confederates, pair scores, or dyad scores. However, using confederates or dyad or pair

scores has two disadvantages: (a) The nature of the dependency itself, which may be of interest, is often overlooked, and (b) information about partner effects or the interaction of subject and partner effects cannot be obtained.

In the next section, we propose a technique that allows for the analysis of measures of the individual behaviors of both subjects and their partners. The technique involves estimating the level of dependency between subject and partner behaviors and taking this dependency into account before estimating and testing group effects. In general, the analysis parallels the logic of a matched-pairs t test. The approach can be generalized to the examination of individual behavior observed in groups larger than two. We consider (and reject) two alternative approaches that do not take dependency into account and point out the types of errors that this neglect induces, as well as two alternative approaches that may or may not be viable.

Analysis of Individual Behavioral Observations in Dyads

The design considered here is one in which three types of dyads are studied: girl–girl pairs (GG), girl–boy pairs (GB for an observation of the girl in such a pair and BG for an observation of the boy), and boy–boy pairs (BB). The mathematical model used basically involves analysis of variance, fixed effects, and two factors with μ as the grand mean, α as the effect of sex of subject, β as the effect of sex of partner, and γ as the group interaction between sex of subject and sex of partner. Since, however, the pairwise correlations are nonzero and the cell variances may be unequal, the usual analytic procedures may be invalid.

The model states that the paired observations in the girl–girl group are indicated by (x, x') with

$$x = \mu + \alpha + \beta + \gamma + \epsilon,$$
$$x' = \mu + \alpha + \beta + \gamma + \epsilon',$$
$$E(\epsilon) = E(\epsilon') = 0,$$
$$\text{var}\ (\epsilon) = \text{var}\ (\epsilon') = \sigma_{11}^2,$$
$$\text{correlation}\ (\epsilon, \epsilon') = \rho_{11}.$$

Observations of the girl–boy pairs are indicated by (x, y) with

$$x = \mu + \alpha - \beta - \gamma + \epsilon,$$
$$y = \mu - \alpha + \beta - \gamma + \eta,$$
$$E(\epsilon) = E(\eta) = 0,$$
$$\text{var}\ (\epsilon) = \sigma_{12}^2, \quad \text{var}\ (\eta) = \sigma_{21}^2,$$
$$\text{correlation}\ (\epsilon, \eta) = \rho_{12}.$$

Observations of the boy–boy pairs are indicated by (y, y') with

$$y = \mu - \alpha - \beta + \gamma + \eta,$$
$$y' = \mu - \alpha - \beta + \gamma + \eta',$$
$$E(\eta) = E(\eta') = 0,$$
$$\text{var}\ (\eta) = \text{var}\ (\eta') = \sigma_{22}^2,$$
$$\text{correlation}\ (\eta, \eta') = \rho_{22}.$$

Now let $m_1 = (x + x')/2$ in the girl–girl group (the order of assignment within same-sex pairs will be seen to be irrelevant), let $m_2 = (x+y)/2$ and $d_2 = (x-y)/2$ in the girl–boy pairs, and let $m_3 = (y + y')/2$ in the boy–boy pairs. Now m_1, m_2, d_2, and m_3 are random variables with

$$E(m_1) = \mu + \alpha + \beta + \gamma$$

where

$$\text{var}\ (m_1) = \frac{\sigma_{11}^2}{2}(1 + \rho_{11}),$$

$$E(m_2) = \mu - \gamma$$

where

$$\text{var}\ (m_2) = \frac{\sigma_{12}^2 + 2\rho_{12}\sigma_{12}\sigma_{21} + \sigma_{21}^2}{4},$$

$$E(d_2) = \alpha - \beta$$

where

$$\text{var}\ (d_2) = \frac{\sigma_{12}^2 - 2\rho_{12}\sigma_{12}\sigma_{21} + \sigma_{21}^2}{4},$$

$$E(m_3) = \mu - \alpha - \beta + \gamma$$

where

$$\text{var}\ (m_3) = \frac{\sigma_{22}^2}{2}(1 + \rho_{22}).$$

The variances of each of these variables, which are rather complicated functions of the popula-

tion variances and correlation coefficients, can be estimated directly and simply from the sample by the sample variances

$$s_{m_1}^2, s_{m_2}^2, s_{d_2}^2, \text{ and } s_{m_3}^2.$$

Using the above equations, the following are estimators of the parameters:

$$\hat{\mu} = \frac{M_1 + 2M_2 + M_3}{4},$$

$$\hat{\beta} = \frac{M_1 - 2d_2 - M_3}{4},$$

$$\hat{\alpha} = \frac{M_1 + 2d_2 - M_3}{4},$$

and

$$\hat{\gamma} = \frac{M_1 - 2M_2 + M_3}{4},$$

where M_1 is the mean computed over the n_1 averaged responses of the girl–girl pairs, M_2 is the mean computed over the n_2 averaged responses, d_2 is the half difference of the responses of the girl–boy pairs, and M_3 is the mean computed over the n_3 averaged responses of the boy–boy pairs. Since statistics that have different subscripts are independent, the standard errors of $\hat{\mu}$ and $\hat{\gamma}$ are estimated by

$$SE_1 = \frac{1}{4}\left(\frac{s_{m_1}^2}{n_1} + \frac{4s_{m_2}^2}{n_2} + \frac{s_{m_3}^2}{n_3}\right)^{\frac{1}{2}},$$

and the standard errors of $\hat{\alpha}$ and $\hat{\beta}$ are estimated by

$$SE_2 = \frac{1}{4}\left(\frac{s_{m_1}^2}{n_1} + \frac{4s_{d_2}^2}{n_2} + \frac{s_{m_3}^2}{n_3}\right)^{\frac{1}{2}}.$$

If the sample variances are consistent estimators of finite population variances, then for large sample sizes the test statistics $\hat{\mu}/SE_1$, $\hat{\alpha}/SE_2$, $\hat{\beta}/SE_2$, and $\hat{\gamma}/SE_1$ are approximately distributed as standard normal deviates (Cramér, 1946; Lindeberg & Levy Theorem, p. 215; Theorem 20.6, p. 254). To ascertain the statistical significance of any of these effects for large sample sizes, one would compare the magnitude of the corresponding test statistic with the critical values of the standard normal distribution.

To this point, minimal assumptions have been made about the distributions of the data. In particular, we have avoided assuming a bivariate normal distribution or equal variances as well as zero correlation coefficients. It should be noted, however, that if the variances are equal and the correlations are zero, then the statistics above are approximately distributed as t statistics. If the size of degrees of freedom is large, there is little difference in referring to critical values of a t statistic instead of those of the standard normal deviate. For small sample sizes, however, one should be aware of these options as well as of the consequences of inappropriately exercising these options.

If variances are equal and correlations are zero, then the degrees of freedom are $n_1 + n_2 + n_3 - 4$. The procedure in this case is only as valid as the assumptions. If variances are unequal or correlations are nonzero, there is considerable evidence that the nominal significance level of the test may differ substantially from the real significance level (Scheffé, 1959, chap. 10). If the data are nonnormally distributed (but the variance–correlation assumptions are met), it is generally believed that the t test is relatively robust. However, even in this instance, there are special cases that belie this belief (Lee & Gurland, 1977).

Alternatively, one can assume that SE_1^2 and SE_2^2 are linear combinations of independent chi-square statistics, statistically independent of the sample means used to estimate μ, α, β, and γ. In this case, the sample statistics are approximately distributed as t statistics with degrees of freedom that can be estimated from the data (Satterthwaite, 1946). Again, however, if the data are not approximately normally distributed, for small samples the sample variances do not necessarily have chi-square distributions, nor are the sample means and variances necessarily independent. Application of this theory may then be risky.

In addition to these analyses for group effects, intraclass correlation coefficients can be computed separately between paired individuals in the girl–girl and boy–boy dyads, and the product-moment correlation coefficient can be computed for the girl–boy dyad (the intraclass form may be inappropriate if the variances of observations on girl and boy in the GB dyad are not equal). Tests of significance for the two types of correlation coefficients

differ only in specification of degrees of freedom ($n - 1$ for intraclass and $n - 2$ for product moment). Not only can one test for the significance of each correlation coefficient but one can also test for the homogeneity of the three correlation coefficients, and, if they are homogeneous, one can test for the significance of their pooled value (Kraemer, 1975).

A detailed example of the full calculation, estimation, and testing procedures is presented in Tables 1 and 2.

Examination of Alternative Approaches

Inappropriate ANOVA Approach

What are the consequences of applying the usual ANOVA procedure for a balanced design ($n_1, n_3 = n, n_2 = 2n$) and ignoring the paired nature of the data? The parameter estimators are identical to those above and remain unbiased. The variance of these estimators, however, may be either underestimated or overestimated (depending on the true variance–covariance structure) by the use of the mean square error from the ANOVA. For example, if all the variances were equal and all the correlation coefficients were equal to a single nonzero ρ, then the mean square error would estimate σ^2, and the variance of $\hat{\gamma}$ would be taken to be $\sigma^2/8n$. In fact, var $(\hat{\gamma}) = \sigma^2(1 + \rho)/8n$. Thus if $\rho > 0$ (i.e., a positive correlation between subjects and partners), the variance is underestimated, and $\hat{\imath}$ (the interaction between subjects and partners) may appear to be more significant than it is; whereas if $\rho < 0$ (i.e., a negative correlation between subjects and partners), the variance is overestimated, and $\hat{\imath}$ (the interaction between subjects and partners) may appear to be less significant than it truly is. Thus, in general, if the correlation between subject and partner is ignored, incorrect statements may be made regarding the significance of one's findings.

Table 1
Frequency of a Toy Offer in an Interactive Experimental Situation[a]

Raw data			Processed data			
GG	GB, BG	BB	m_1	m_2	d_2	m_3
3, 10	1, 2	2, 1	6.5	1.5	−.5	1.5
5, 0	0, 0	2, 1	2.5	.0	.0	1.5
2, 2	0, 9	1, 1	2.0	4.5	−4.5	1.0
1, 5	3, 2	3, 3	3.0	2.5	.5	3.0
3, 0	5, 2	0, 2	1.5	3.5	1.5	1.0
2, 3	2, 3	2, 0	2.5	2.5	−.5	1.0
2, 3	5, 5	1, 4	2.5	5.0	.0	2.5
3, 0	0, 1	5, 4	1.5	.5	−.5	4.5
2, 7	3, 3	1, 1	4.5	3.0	.0	1.0
2, 3	5, 5	1, 0	2.5	5.0	.0	.5
1, 5	4, 3	1, 4	3.0	3.5	.5	2.5
5, 8	2, 0	0, 0	6.5	1.0	1.0	.0
	1, 2			1.5	−.5	
	3, 14			8.5	−5.5	
	4, 1			2.5	1.5	
	7, 2			4.5	2.5	
	0, 0			.0	.0	
	0, 0			.0	.0	
	0, 0			.0	.0	
	3, 1			2.0	1.0	
	1, 2			1.5	−.5	
M			3.21	2.52	−.19	1.67
SD			1.72	2.16	1.79	1.25

Note. G = girl; B = boy. Intragroup correlation coefficients were .33 (*ns*), .44 ($p < .05$), and −.19 (*ns*) for the GG, GB plus BG, and BB groups, respectively. There was no significant deviation from homogeneity of correlation: $\chi^2 = 3.10$. For the pooled correlation coefficient, $\hat{\rho} = .25$.
[a] Data are from Jacklin and Maccoby (1978).

Table 2
Estimates and Tests of Effects for Frequency of a Toy Offer[a]

Parameter	Estimator	*SE*	*z*	Estimated *df*[b]
μ	2.481	.281	8.829**	34
α	−.480	.249	1.928*	38
β	−.290	.249	1.165	38
γ	−.403	.281	.150	34

[a] Data are from Jacklin and Maccoby (1978).
[b] Using the method described in Satterthwaite (1946)
* $p < .10$.
** $p < .001$; the effect of the mean estimator's being significantly different from zero is trivial in this case, since only positive scores were used. However, if negative and positive scores had been used, the estimator significance might be useful.

Multiple t-Test Approach

One might also consider comparing (e.g., using *t* tests) the responses of boys in same-sex dyads (averaging paired responses) with those

of boys in mixed-sex dyads (BB vs. GB) and similarly consider comparing BB versus BG, BB versus GG, BG versus GG, and GB versus GG). Since subjects' responses in different groups are independent, these would be valid tests. There are five such tests, with the proposed multiple t tests nonindependent. In such a case, the probability that one or another of the tests will exceed the stated significance level by chance may be quite high. However, this is not the crucial point. The main problem lies in the fact that one can extract from these test results no clear evidence as to which of the factors of interest (sex of subject, sex of partner, or interaction) is operative, since each procedure tests some combination of factors. For example, the test comparing the boys' responses in the BB and BG dyads tests whether $\alpha = \gamma$. If the test turns out to be significant, it is not clear whether $\alpha = 0$ and $\gamma \neq 0$, whether $\alpha \neq 0$ and $\gamma = 0$, or whether both are nonzero but equal to different values. Whether or not the sex of partner effect equals the interaction effect is in general simply not of research interest.

Discarding-Data Approach

One may also discard one randomly selected subject from each dyad to ensure independence of the data used in analysis. However, computational simplicity is in this case achieved at considerable loss of power and, in addition, with a loss of information about the dyadic interaction itself, that is, about the pairwise correlations, which may be of interest.

Multivariate Analysis of Variance

Another valid approach to the analysis entails regarding the original sample as one from a bivariate distribution with means and covariance structure as specified. If the distribution is specifically bivariate normal with identical covariance structure in the three groups (BB, BG, and GG), one can use a multivariate ANOVA approach (Anderson, 1958, p. 215–221). For small sample sizes, this procedure is preferable if the assumptions are satisfied, but is risky otherwise.

Generalization to Triads and Beyond

The approach detailed for dyads can be generalized to the situation in which subjects are of two types (girls and boys) but are combined in groups of size three or more. The principles used in the case of dyads are readily extended to larger groups, but the notation becomes cumbersome. We thus sketch only briefly how this generalization can be effected. Table 3 presents a mathematical model for this situation.

Each group comprises k members, and there are $k + 1$ such groups indexed by the number of girls in the group: $j = 0, 1, 2, \ldots, k$. In the model, α is the sex of subject effect, β_j is the main effect of that subject's partnership group (with $k - 1$ members), comprising $j - 1$ girls and $k - j$ boys, and γ_j is the interaction effect between sex of subject and such a partnership group ($\sum \beta_j = \sum \gamma_j = 0$; $j = 1, 2, \ldots, k$). Thus one notes that the response of a boy in a group of $j - 1$ girls and $k - j + 1$ boys is parameterized in terms of the same parameters (β and γ) as that of a girl in a group of j girls and $k - j$ boys.

We assume that the expected response of all girls in any group is the same, as is that of all boys in a group. Thus each k-dimensional response vector, for purposes of estimating the

Table 3
Model for Individual Responses in Groups of Size k

Index j	Type of group: No. Girls	Type of group: No. Boys	Individual response: Girls	Individual response: Boys	No. Groups Observed	Mean response: Girls	Mean response: Boys
0	0	k	—	$\mu - \alpha + \beta_1 - \gamma_1 + \epsilon'$	n_0	—	$\bar{Y}_{\cdot 1}$
1	1	$k - 1$	$\mu + \alpha + \beta_1 + \gamma_1 + \epsilon$	$\mu - \alpha + \beta_2 - \gamma_2 + \epsilon'$	n_1	$\bar{X}_{\cdot 1}$	$\bar{Y}_{\cdot 2}$
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$
k	k	0	$\mu + \alpha + \beta_k + \gamma_k + \epsilon$	—	n_k	$\bar{X}_{\cdot k}$	—

parameters, can be reduced to a bivariate vector $(X_{ij}, Y_{i(j+1)})$ in which X_{ij} is the average response of girls in the ith group of type j $(i = 1, 2, \ldots, n_j)$ and $Y_{i(j+1)}$ is the average response of boys in such a group. Thus no matter what the size of the group, the problem can be reduced to that of considering a bivariate response.

Within a group there are only three intersubject correlation coefficients of interest: that of the error components between a pair of girls, that between a pair of boys, and that between a boy and a girl. When these correlation coefficients are nonzero, as one would expect, X_{ij} and $Y_{i(j+1)}$ are correlated responses.

If the data are reorganized in terms of a two-way layout (Sex of Subject × Type of Partnership Group), the process of obtaining unbiased estimators of the parameters is clear (see Table 4).

Table 4
Means Computed From Groups of Size k

Sex of subject	No. of girls in partnership group: 0	1	2	⋯	⋯ $k-1$	Mean
Girl	$\bar{X}_{.1}$	$\bar{X}_{.2}$	$\bar{X}_{.3}$	⋯	⋯ $\bar{X}_{.k}$	$\bar{X}_{..}$
Boy	$\bar{Y}_{.1}$	$\bar{Y}_{.2}$	$\bar{Y}_{.3}$	⋯	⋯ $\bar{Y}_{.k}$	$\bar{Y}_{..}$
Mean	$\bar{Z}_1$	$\bar{Z}_2$	$\bar{Z}_3$		$\bar{Z}_k$	M

Note. Each mean in the first row is correlated with the mean in the second row that is one column to the right (e.g., $\bar{X}_{.1}$ with $\bar{Y}_{.2}$); $\bar{X}_{.j} = \sum_i X_{ij}/n_j$, $\bar{Y}_{.j} = \sum_i Y_{ij}/n_{j-1}$, $\bar{X}_{..} = \sum_j \bar{X}_{.j}/k$, $\bar{Y}_{..} = \sum_j \bar{Y}_{.j}/k$, $M = (\bar{X}_{..} + \bar{Y}_{..})/2$, and $\bar{Z}_j = (\bar{X}_{.j} + \bar{Y}_{.j})/2$.

Thus

$$\hat{\mu} = M,$$

$$\hat{\alpha} = \bar{X}_{..} - M,$$

$$\hat{\beta}_j = \bar{Z}_j - M \quad \text{where} \quad j = 1, 2, \ldots, k, \text{ and}$$

$$\hat{\gamma}_j = \bar{X}_{.j} - \bar{Z}_j - \bar{X}_{..} + M \quad \text{where} \quad j = 1, 2, \ldots, k.$$

The problem lies in the estimation of standard errors for these estimators, since they comprise both dependent and independent sample means. The procedure is illustrated by the calculation for, say, $\hat{\beta}_2$.

First $\hat{\beta}_2$ is re-expressed in terms of sample means as

$$\hat{\beta}_2 = (\bar{X}_{.2} + \bar{Y}_{.2})/2 - (\sum_{j=1}^{k} \bar{X}_{.j} + \sum_{j=1}^{k} \bar{Y}_{.j})/2k.$$

Correlated means are isolated, that is,

$$\hat{\beta}_2 = (2k)^{-1}\{[(k-1)\bar{X}_{.2} - \bar{Y}_{.3}] + [(k-1)\bar{Y}_{.2} - \bar{X}_{.1}] - \sum_{j=3}^{k-1} (\bar{X}_{.j} + \bar{Y}_{.(j+1)}) - (\bar{Y}_{.1}) - (\bar{X}_{.k})\}.$$

In this case, each bracketed term is independent of any other bracketed term, since the terms arise from different groups. Thus the variance of $\hat{\beta}_2$ is the sum of the variances of the bracketed terms divided by $4k^2$. The variance of any one of these terms, for example, that of

$$[(k-1)\bar{X}_{.2} - \bar{Y}_{.3})],$$

is obtained as follows.

For each of the n_2 groups observed comprising two girls and $k - 2$ boys we compute

$$U_i = (k-1)X_{i2} - Y_{i3}, \quad \text{where} \quad i = 1, 2, \ldots, n_2.$$

The variance estimate of σ_U^2 is then the sample variance of these observations, s_U^2. The term of interest,

$$(k-1)\bar{X}_{.2} - \bar{Y}_{.3} = \bar{U},$$

has population variance σ_U^2/n_2, estimated by s_U^2/n_2.

In this way the variance estimates of each of the bracketed terms are compiled and combined to yield the variance estimate of $\hat{\beta}_2$. Once again, if the sample variances are consistent estimators of finite population variances, the large sample distribution of the ratio of the statistic to its standard error under the null hypothesis is approximately standard normal. As above, under certain circumstances the small sample distribution of these statistics may be either exactly or approximately a t distribution.

Summary

The study of social behavior without confederates is complicated by the dependency of subjects' and partners' behaviors. We have suggested a statistical approach that takes

into account this dependency. Although we have illustrated the approach with data from dyads, the method can be generalized to groups of any size.

We have discussed the problems encountered with alternative statistical analyses. The most common approach in the literature is to use an ANOVA without taking into account the dependency of the data. Even if all the other ANOVA assumptions are met (equal variances and balanced design), the test for the interaction term, for example, will be biased depending on the amount and direction of dependency (correlation) that exist. Positive correlations lead to an overestimate of the significance of the ANOVA interaction term; negative correlations lead to an underestimate of the significance of the ANOVA interaction term. A second approach we discussed was the multiple *t*-test approach. The problem with this approach is that it does not give clear evidence of which factors of interest account for the results. A third approach is to drop half the subjects from the analysis to eliminate the dependency. One problem with this approach is a loss of power of the test used, but perhaps a more serious problem is that the actual correlations between subject and partner may be lost.

Finally, we note that all of these approaches represent attempts to reduce what is in general a complex multivariate analysis problem to a series of relatively simple univariate analysis problems. In certain circumstances (multivariate normality and certain covariance structures) the multivariate approach is not so complex as to discourage its use and in these cases is preferable.

Interdependence of subjects' and partners' behaviors reflects the real social situation. In some cases, if we are to understand the dynamics of social behavior, the use of confederates may not be the best choice, even when it is possible. The analytic procedures, however, should be appropriate to the nature of the data.

Obsessive–Compulsive Personality: A Review

Jerrold M. Pollak
Boston College

A review of the term *obsessive–compulsive personality* (or *anal character*) is presented. Statistical studies of obsessive–compulsive personality conducted over approximately the last two decades are then reviewed, emphasizing the extent to which they support theory, clinical observation, and description. Evidence is still needed on precise etiological determinants, and persuasive evidence in favor of classical psychoanalytic theories about etiology is lacking. Empirically based findings to date, however, are congruent with clinical observation, description, and prediction regarding the salient behavioral characteristics and character styles of obsessive–compulsive individuals.

The obsessive–compulsive personality or *anal character*, as it is sometimes termed, came under close scrutiny by Freud and his colleagues (Abraham, 1921/1953; Freud, 1908/1963; Jones, 1918/1961). Carr (1974) credited Esquirol (cited in Carr, 1974), who worked in the early part of the 19th century, with the first publication relating to compulsions and similar phenomena. According to the early Freudians, the anal character, as they referred to it, arises out of conflicts between parents and child over bowel training in the 2nd to 3rd year of life. The introduction of bowel training was thought to bring with it an inevitable conflict between the child's desire to freely manipulate elimination (expulsiveness) and retention (retentiveness) and the need of the child's primary caretakers to regulate their child's anal activities and expressions in line with prevailing cultural and societal standards of cleanliness and impulse control. If the primary caretakers prove to be too punitive, impatient, and intolerant of their charge's willfulness and autonomy, or if the training comes either too early or too late or is experienced as inordinately frustrating or gratifying, the inevitable struggle over bowel control intensifies. According to classical analytic theory, this may very well establish the groundwork for anal fixations and hence the development of a predominantly anal or obsessive–compulsive character structure in the child.

For Freud and for all later analytic and nonanalytic clinicians, obsessional personality or anal character is to be carefully distinguished from the psychiatric syndrome of what has been called obsessive–compulsive or obsessional neurosis. In an obsessional neurosis the individual suffers from persistent intrusion of undesired thoughts (obsessions) or urges and actions (compulsions) that he or she finds extremely difficult, if not impossible, to control and ultimately stop. Following Salzman (1968), the obsession may be viewed as a persistent ritualized thought pattern, whereas the compulsion is a persistent ritualized behavior pattern. Either or both may be salient in the clinical picture, and anxiety and distress usually are concomitants of the disorder.

Individuals with a predominantly obsessive–compulsive personality are considered asymptomatic, that is, what defines the individual consists of particular constellations of traits, defenses, and life-style and not the presence of psychiatric symptomatology.

While obsessive–compulsive neurosis is a relatively rare phenomenon (Templer, 1972), obsessive–compulsive personality or anal char-

Appreciation is extended to Veronika Neudachin for her editorial assistance.

acter structure is not. In fact, one could argue that in Western culture obsessive–compulsive personality is one of the, if not the predominant, social character structures, embodying as it does so much of the general world view of the Protestant Work Ethic and capitalist social and economic organization (Honigmann, 1967).

Obsessive–compulsive personality has also been observed to prevail in some non-Western but relatively advanced industrial societies, such as Japan (Gorer, 1943), and is very much in evidence within various professional groups and specialty occupations and among individuals in bureaucratic and managerial positions. It could be said as well that many of the traits characteristic of obsessional personalities, for example, perseverance, industriousness, thriftiness, ambition, self-control, and so on, are highly regarded and rewarded within capitalistic, technological societies, serve to promote in their possessors feelings of self-worth and acceptability, and generally provide them with a foundation for emotional stability and relative resistance to stress (Paykel & Prusoff, 1973).

Freud (1908/1963) delineated one particular constellation of traits, namely, obstinacy, parsimony, and orderliness, that constitute the core of what he termed the *anal retentive* or *anal character* type and that arise from sublimations of and reaction formations against infantile anal erotic impulses that press for expression. In Freud, orderliness refers to both exceptional bodily cleanliness and a high degree of reliability and conscientiousness in the performance of all actions, however inconsequential. Parsimony involves frugality and, in the extreme, stinginess and avarice, whereas obstinacy involves strong tendencies to be negativistic, defiant, and even hostile in relation to authority figures. According to Freud, orderliness develops from the internalization of parental demands for bowel control, whereas parsimony develops from the continuation of the infantile tendency to retain feces, both because of the erotic pleasure that accompanies retention and because of the fear of losing the overvalued product. Freud viewed obstinacy as developing from resistance to parental demands. In the traditional psychoanalytic model, considerable aggression, that is, anal sadistic impulses and attitudes, is generated in the child as a result of his or her struggle to insure autonomy. When this struggle leads to fixations or developmental arrests at the anal stage, the infantile unresolved aggression is expressed in later life in any number of ways, for example, in passive–aggressive withholding behavior (or other indirect means of defying the wishes or dictates of others) or in the adoption of extremely conventional, oversocialized or reactionary attitudes via reaction formation and identification with the aggressor. The adoption of reactionary attitudes is oftentimes linked with an aggressive, hypercritical, and controlling attitude toward others. Regardless of the exact form taken by infantile aggression in specific individuals, ambivalent attitudes toward the expression of hostile feelings and impulses particularly, but also toward all manifestations of the affect and impulse life, are thought to be paramount in the personality makeup of the adult obsessive.

The traits, defenses (undoing, reaction formation, intellectualization, and isolation), and life-styles viewed as characteristic of anal characters or obsessive–compulsive personalities have been further elaborated by later analysts with more refined theoretical formulations, case history data, and analyses of responses to projective tests like the Rorschach test (Fenichel, 1945; Rado, 1959; Schafer, 1954; Shapiro, 1965). Despite some ambiguities and inconsistencies in the voluminous clinical literature, there appears to be considerable consistency in the personality descriptions that emerge. This is true even when one compares psychoanalytic descriptions of the anal character with descriptions of the obsessive–compulsive character of obsessive personality that emerge from less heavily psychoanalytically influenced theoreticians and practitioners. The latter accept the analytic description of the character, but do not necessarily agree with its etiologic assumptions concerning psychogenesis in the anal stage of psychosexual development. Ingram (1961a), for instance, compared descriptions of the obsessive personality found in leading psychiatric texts with descriptions of the anal character given in the classical psychoanalytic

papers of Freud, Abraham, and Jones and found highly similar descriptions with numerous features in common, for example, the characteristics of orderliness, persistence, and rigidity. For descriptive purposes Ingram felt there was no point in distinguishing between the two terms. The terms *obsessional*, *obsessive*, or *obsessive–compulsive* personality appear to be the preferred terms insofar as no etiologic assumptions are implied by them.

In his review of descriptive features, Ingram emphasized the following composite description of obsessive individuals:

People who manifest *obstinacy* are persevering, thorough, reliable, overconscientious, and have considerable qualities of endurance and drive. They are dogged and persistent. All of this may lead them to be called obstinate, stubborn, or defiant. Added to this is a quality of self-willed independence that leads to a desire to do things their own way and to a dislike of interference. They are rigid and inflexible, particularly in terms of ideals, values, and standards of conduct for themselves as well as others. They are not emotionally demonstrative and may be cold, aloof, and distant. They are often critical, controlling, and in the extreme, power loving.

Individuals who demonstrate *inconclusiveness* are indecisive, vacillate in behavior and thought, cannot leave well enough alone, and make unsatisfying attempts to reach order and perfection. They are always busy and never finished and feel harassed by responsibilities and obligations. They repeat and check their work repeatedly and needlessly, and they continuously weigh the pros and cons of decisions. They fear error, are afraid of making mistakes or omissions, have strict moral scruples, and fear violating the social code. In general, they are uncertain of themselves, are insecure, are prone to worry and doubt, and can be hesitant; but they often try to conceal these traits.

People who display *orderliness* are overorderly, live by routine, and become easily upset when their routine is disturbed by unforeseen events or circumstances. They are meticulous, perfectionistic, and sticklers for precision. They are fond of indexing, tabulating, organizing, and planning and crave accuracy, symmetry, and rationality.

Individuals who exhibit *parsimony* are frequently avaricious, particularly with regard to possessions, money, and time, all of which are not to be wasted.

The review of the literature presented in the following pages focuses on statistically based research studies of obsessive–compulsive personality conducted over the past two decades or so that are judged to be relevant to the descriptive, psychogenetic, and psychodynamic considerations that have emerged primarily from theory and clinical observation.

Empirical Studies Relevant to the Etiology of Obsessive–Compulsive Personality

A number of investigators have sought to substantiate relationships between toilet training practices and the development of anal character traits as originally proposed by Freud (e.g., Beloff, 1957; Bernstein, 1955; Durrett, 1959; Finney, 1963; Hetherington & Brackbill, 1963; Holway, 1949; Huschka, 1942; Kline, 1969; D. R. Miller & Swanson, 1966; Sears, Rau, & Alpert, 1965; Sewell, Mussen, & Harris, 1955; Straus, 1957; Whiting & Child, 1953). The majority of these studies have focused largely on the age toilet training was initiated, the age it was brought to completion, and the degree to which it may have been inordinately lax or severe. The designs typically involved the collection of retrospective accounts, usually by mothers, of the toilet training period in an attempt to relate these parental recollections of when and how training proceeded to the degree of the offspring's anal orientation, as measured by teacher and parent ratings, response to anality questionnaires, and performance on various behavioral tests (S. Fisher & Greenberg, 1977).

A review of these studies offers, at best, meager support for the hypothesized relationship between toilet training practices and the development of anal or obsessive–compulsive character structure. Orlansky (1949) concluded that knowledge of sphincter training was insufficient to substantiate or disprove the Freudian position. Sewell et al. (1955) attempted to relate toilet training practices to personality assessments made at

5 years of age, but found no evidence for the Freudian view. Beloff (1957) found that the personality traits of orderliness, parsimony, and obstinacy occurred together, but could not find significant relationships between how coercively toilet training was carried out, as assessed through interviews of mothers of college students, and student and peer ratings of anal characteristics. In a review of child-rearing practices, O'Connor and Franks (1960) reported no conclusive evidence for the Freudian interpretation. Studies subsequent to that review (e.g., Hetherington & Brackbill, 1963; Finney, 1963; Sears et al., 1965) also indicated that reported parental accounts of toilet training practices were not related to ratings of children's anal characteristics. Moreover, in a series of studies, Gottheil and Stone (1968, 1974) and Stone and Gottheil (1975) could find, at best, only a "slight preferential association" between anal personality patterns and patterns of bowel habits in samples of normal, neurotic, and psychosomatically involved outpatients, that is, bowel habit questionnaire items did not load highly on the anal trait factor that was identified. Kline (1968), however, did report significant positive relationships between a measure of anal eroticism derived from the Blacky Pictures (Blum, 1949) and several measures of obsessional traits and symptoms (viz., measures from Sandler & Hazari, 1960, and Beloff, 1957, and his own AI3 Scale of Anality).

Although it appears that there is little, if any, empirical evidence for the classical psychoanalytic position on the etiology of the obsessive–compulsive or anal character type, there are suggestions in clinical observation and in some of the same studies that failed to support the Freudian point of view of relationships between anal character traits in the child and the existence of anal characteristics in the parents (Beloff, 1957; Finney, 1963; Hetherington & Brackbill, 1963). Beloff administered a questionnaire concerned with anal traits to a sample of male and female college students and their mothers and found positive relationships between parental anal orientation and the anal orientation of the children.

Hetherington and Brackbill administered a questionnaire measuring Freud's anal triad, namely, obstinacy, orderliness, and parsimony, to a sample of fathers and mothers. Their male and female children's anality was assessed by performance on a series of tasks measuring anal behaviors such as parsimony, obstinacy, and perseverance. Significant positive correlations were found between degree of anality in mother and daughter but not in mother and son. No significant relationships were found between a father's anality and that of his children of either sex. Speculating that strict toilet training is simply one expression of a more general pattern of parental rigidity, Finney found, as predicted, that clinicians' ratings of general rigidity in a sample of mothers bore a significant positive relationship to the degree of the child's anal orientation.

The results of these studies, which are indicative of comparable degrees of anal orientation in children and their parents, suggest a number of possibilities regarding etiology. It may be that obsessive–compulsive personality or anal character structure emerges from repeated contact, association, and clashes throughout childhood between the child and figures such as parents, teachers, and relatives directly involved in caretaking responsibilities, who are themselves fairly rigid, controlling, and generally obsessional in their style of relating to the children in their charge. As Carr (1974) has pointed out, even if a relationship between rigid toilet training practices and obsessional traits could be shown, this association could easily be interpreted as a function of childhood training in general rather than of specific repressive toilet training. This point of view is not inconsistent with the idea that the effect of a rigid, obsessional parental orientation could very well be maximal before or during the toilet training phase, when unresolved anal conflicts in one or both parents are stirred up anew, leading to increased anxiety and more pronounced recourse to obsessional behavior as a defense against the impact of the stressful circumstances (S. Fisher & Greenberg, 1977). This could occur even if the primary caretakers did not begin toilet training particularly early or late. It may be, then, that toilet training practices are not causal in any

strict sense, but are a correlate of a larger and more influential child-rearing pattern. In this view, obsessive–compulsive style is seen as largely socially learned behavior that results from the imitation and modeling of significant others over a number of years throughout the childhood period.

One cannot discount, as well, the possible role played by some as yet vaguely defined constitutional factors in the etiology of obsessive–compulsive personality. Freud (1908/1963) himself made reference to constitutional influences that might result in an especially intense inborn erotic sensitivity in the anal zone that by itself or in interaction with experiences during the toilet training phase results in the development of a predominantly anal adult personality orientation.

In a review of research findings on obsessive–compulsive neurosis, Templer (1972) concluded that, although there is a high incidence of various types of psychopathology among relatives of obsessive–compulsive neurotics, the possible etiological role played by genetic or other constitutional factors is unclear. This point of view is shared by Carr (1974). In the case of the development of obsessive–compulsive personality, the possible role played by constitutional influences still remains in the realm of speculation because, to date, there has been little empirical research in this area. A study by Hays (1972), however, of the family pedigrees of 17 psychiatric patients, mostly female, that carried a diagnosis of psychotic depression and had premorbid obsessive–compulsive personalities did find evidence to support an interaction effect of genetic predisposition, sex of the child, and child-rearing style in the genesis of obsessive–compulsive personality.

Some theorists and clinicians stress the need for obsessive–compulsive personality style as a character defense or armor for the ego against the ambiguities, uncertainties, and anxieties inherent in human existence (e.g., Becker, 1974; M. H. Miller & Chotlos, 1960; Salzman, 1968; Strauss, 1966). There is yet, however, no statistical evidence to support the theorizing of these clinicians, who work largely within an existential–phenomenological framework that rarely generates statistical data.

Measurement of Obsessive Compulsiveness

Over the past two decades, several questionnaires and scales have been devised that purport to measure obsessional traits and characteristics (Allen & Tune, 1975; Beloff, 1957; Blum, 1949; Caine & Hawkins, 1963; Comrey, 1965; Cooper, 1970; Gottheil, 1965b; Grygier, 1956; Kline, 1969; Lazare, Klerman, & Armor, 1966, 1970; Sandler & Hazari, 1960). Kline (1969) argued that there has really not been an abundance of empirical research on obsessional personality, primarily because there is no fully accepted measure of obsessional traits or obsessional symptoms. Most, if not all, of the existing scales are not standardized, nor is there sufficient evidence for their reliability and validity to justify a rational choice of one over the other. According to Kline the major personality inventories, like the Sixteen Personality Factor Questionnaire (Cattell & Eber, 1957), the Eysenck Personality Inventory, the Maudsley Personality Inventory, and the Minnesota Multiphasic Personality Inventory (MMPI), do not contain a measure of obsessional traits and characteristics. The Psychasthenia scale of the MMPI, designated as Scale 7, is sometimes referred to as a measure of obsessive–compulsiveness; however, there is good reason to suspect that the Psychasthenia scale is more a general measure of classically neurotic concerns, preoccupations, and characteristics, namely, anxiety, withdrawal, immobilization, agitation, and so on, rather than a specific measure of obsessive–compulsive behavioral tendencies (e.g., Dahlstrom, Welsh, & Dahlstrom, 1972; Drake & Oetting, 1959). One of the more promising measures to date is the Lazare-Klerman Trait Scales (Lazare et al., 1966, 1970), a factor analytically derived instrument that purports to measure obsessional, hysterical, and oral dependent personality. This self-report inventory contains 140 true–false items that are scored into 20 trait scores, each based on seven items. These 20 traits are reported in four separate factor analytic studies to combine to three orthogonal factors that closely mirror obsessive, hysterical, and oral character traits, as described in the clinical literature (Lazare et al., 1966, 1970; Paykel &

Prusoff, 1973; Van Den Berg & Helstone, 1975).

Empirical Validation of Obsessive–Compulsive Personality

Clinical descriptions are highly consistent in terms of the defenses, traits, and behavioral styles thought to be defining characteristics of the obsessive–compulsive personality. The findings of statistical studies have in the majority of cases generally supported the descriptions of the anal trait clusters found in the clinical studies. The bulk of these studies have been of the correlational and factor analytic type (Barnes, 1952; Beloff, 1957; Brooks, 1969; Comrey, 1965; Cooper & Kelleher, 1973; Finney, 1961, 1963; Gottheil, 1965b; Gottheil & Stone, 1968; Hetherington & Brackbill, 1963; Kline, 1968; Lazare et al., 1966, 1970; Mandel, 1958; Paykel & Prusoff, 1973; Rapaport, 1955; Sandler & Hazari, 1960; Schlesinger, 1963; Sears, 1943; Stagner, Lawson, & Moffitt, 1955; Stagner & Moffitt, 1956; Stone & Gottheil, 1975; Van Den Berg & Helstone, 1975).

Finney (1961, 1963) and Beloff (1957) found the traits of obstinacy, parsimony, and orderliness to be correlationally related in the children they studied.

Barnes (1952), Stagner et al. (1955), and Stagner and Moffitt (1956) sought to show through factor analytic methods that traits related to the psychosexual stages delineated in Freudian theory were empirically grouped in adult subjects. The results of these early factor analyses must be viewed as equivocal and difficult to accurately interpret because of inconsistent definitions of psychosexual stages and traits and the dubious adequacy of the measures used (Gottheil & Stone, 1968). In the study by Barnes, a *meticulous* rather than an anal factor per se was identified using the responses of 266 male college students to lists of items composed for the study. However, grouped together on this factor were traits of orderliness, reliability, law abidance, and cleanliness, in addition to meticulousness. Rigidity, sadism, and defiant resentment loaded on another factor termed *externalized aggression*.

Other factor analytic investigations appear to be more consistent with theory and clinical description. Schlesinger (1963) performed a factor analysis of 154 items taken from various anality questionnaires and extracted 12 factors, namely, responsibility in dealing with others, regularity and meticulousness, retentiveness as a style of life, obstinacy, rigidity, frugality, concern about dirt and contamination, orderliness, self-righteous hostility and competitiveness, anxiety over possible loss of control, sensitivity to smells, and retentiveness in relation to possessions. Cooper and Kelleher (1973) carried out a principal-components analysis of the Leyton Obsessional Inventory (Cooper, 1970) using approximately 300 normal subjects divided by sex and nationality (Irish and English). Three distinct components were derived from four separate analyses and termed (a) concern with being clean and tidy, (b) feeling of incompleteness, (c) checking and repetition. The second component appeared to relate to a need for closure, as reflected in the following item: "Even when you have done something carefully, do you often feel that it is somehow not quite right or complete?" Other less distinct components were found, one of which suggested the label *methodical*.

In studies by Lazare et al. (1966, 1970), alluded to above, factor analysis was employed to explore three personality patterns derived from psychoanalytic theory: oral, obsessive, and hysterical. The three personality patterns were defined by approximately 20 traits obtained from a review of the clinical literature. Each of these traits was then reliably measured from groups of true and false items rated by samples of female psychiatric inpatients and outpatients. The traits so measured formed three clusters that corresponded quite closely to psychoanalytic descriptions of oral, obsessive, and hysterical personality patterns. In the earlier study (Lazare et al. 1966), all of the defining traits of the obsessive personality factor were correctly predicted from theory, for example, orderliness, parsimony, rejection of others, emotional constriction, obstinacy, severe superego, rigidity, and perseverance. One predicted obsessive trait, self-doubt, however, only had a factor loading of .12. In their later study, Lazare

et al. (1970) replicated their earlier findings with the exception of the trait of obstinacy. Virtually identical defining traits have been reported by Paykel and Prusoff (1973), who used the responses of male and female recovered depressives to the Lazare-Klerman Trait Scales, and by Van Den Berg and Helstone (1975), who used the Lazare-Klerman Trait Scales in Holland with samples of psychiatric and normal females.

Gottheil (1965a) sought to investigate the extent to which mental health professionals agree in their use of the terms *anal* and *oral* character. A group of psychiatrists and clinical psychologists ($N = 20$) completed questionnaires composed of items derived from clinical descriptions of oral and anal character types and then were asked to predict how a typical oral character would answer the oral questionnaire and how an anal character would typically answer a questionnaire on anal character traits. The degree of consistency demonstrated in the responses of the professional subjects was found to be highly significant statistically, suggesting that mental health experts possess similar conceptions of these character types. Significant agreement was also found among the subjects on a majority of the items that constituted the two questionnaires ($p < .03$). Whereas in both instances agreement was quite high, there was less agreement on the conceptualization of the oral character than of the anal character, suggesting that the concept of the latter has been more clearly and unambiguously described.

In another study, Gottheil (1965b) administered his newly constructed oral and anal questionnaires to 200 army enlisted men. Item analyses indicated that the various characteristics attributed by expe-t judges to the anal and oral character types are empirically associated in the responses of normal adult male subjects.

In one factor analytic study using the same sample of army recruits, Gottheil and Stone (1968) derived an oral and an anal trait factor from responses both to the items constituting the oral and anal trait questionnaires and to items concerned with mouth and bowel habits. Oral and anal subfactors were also derived that were quite consistent with psychoanalytic descriptions. The five anal subfactors identified were termed (a) rigidity; (b) obsessive rumination; (c) perfectionism (which includes orderliness, persistence, and a tendency to be critical); (d) parsimony, possessiveness, and checking and rechecking; and (e) a practical point of view. However, in the overall questionnaire factor analysis, the oral and anal trait factors were weak. Together they accounted for only 5.3% of the variance in the total set of items. Moreover, only 23% of the variance in the anal trait scale was accounted for by the five anal trait subfactors that were extracted. Thus, despite the kinds of items selected, neither anal nor oral character structure emerged as the strongest organizing factor. All of these results were for the most part confirmed in a later study (Stone & Gottheil, 1975) that factor analyzed the responses of samples of neurotic and psychosomatically involved outpatients to the same sets of items employed in the previous study.

Studies by Gottheil (1965b), Gottheil and Stone (1974), and Kline (1967) provide evidence that obsessional character traits are normally distributed in samples of normals and of neurotic and psychosomatic patients. Therefore, adult subjects that constitute both normal and clinical groups cannot be characterized as either having or not having obsessive tendencies, but rather must be characterized as having more or less of them.

Obsessional Symptoms Versus Obsessional Personality

Several studies have addressed the issue of whether obsessional symptoms can be reliably differentiated from obsessional personality traits and characteristics. As discussed in the Introduction, the distinction between personality and symptoms was emphasized by Freud and his contemporaries, as well as by virtually all later clinicians.

Using a sample of 100 neurotic patients, approximately equally divided between men and women, Sandler and Hazari (1960) factor analyzed responses to 40 items related to obsessive–compulsive character traits and symptoms and found two relatively inde-

pendent, orthogonal personality constellations or dimensions quite similar to the clinical distinctions between obsessional character traits and obsessional neurotic symptomatology. The items that loaded on the character trait dimension present a picture of an exceedingly systematic and methodical person who likes a well-ordered life, is consistent and punctual, and is meticulous in his or her use of words. The individual dislikes half-done tasks and finds interruptions in plans and goal-directed activity irksome. He or she pays much attention to detail and has a strong aversion to dirt. These characteristics are well integrated in the personality, that is, they are ego syntonic and are frequently viewed as a source of pride and esteem by their possessors.

The other dimension Sandler and Hazari identified corresponded well to descriptions of obsessional neurotic symptomatology, for example, when life is severely disrupted by the intrusion of unwanted thoughts and compulsive acts and by worry, doubt, and procrastination. Unlike the obsessional traits, these unwanted thoughts and impulses were experienced as alien and disturbing. In psychoanalytic terms, the traits represent a successful or adaptive ego defense, whereas the symptoms are evidence of a breakdown in defense mechanisms (Kline, 1967). Sandler and Hazari concluded that although the two dimensions were orthogonal, this does not necessarily mean that in many instances subjects will not show a mixture of both dimensions; nor does it necessarily imply that both do not share common dynamics and etiology, for example, conflicts over anal urges. Subsequent studies by Foulds, Caine, Adams, and Owen (1965), Kline (1967), and Meares (1971) found evidence to support Sandler and Hazari's original distinction between ego-syntonic traits and ego-dystonic (or alien) symptomatology. Slade (1974) similarly concluded that factor analytic investigations in which both obsessional-trait and obsessional-symptom items have been included strongly suggest the existence of separate trait and symptom factors. Whether a single trait and a single factor emerge or a number of both factors emerge may be primarily dependent on the range of behavior studied.

The results of two studies (Ingram, 1961b; C. M. Rosenberg, 1967) suggest that there is some relationship between obsessional neurosis and obsessional personality. Rosenberg investigated the personality characteristics of 47 obsessional neurotics by means of psychiatric ratings and performance on selected personality inventories. Of this sample, 25 were judged to have an obsessional premorbid personality, which was quite congruent with clinical descriptions, that is, orderly, rigid, obstinate, dependable, pedantic, and so forth. Psychometric studies like those of Sandler and Hazari (1960), however, do suggest the independence of obsessional illness and obsessional character. Moreover, clinical observation suggests that at least some obsessional neurotics never could be said to have had a premorbid obsessional character makeup (e.g., Rack, 1977). In addition, as Paykel and Prusoff (1973) pointed out, obsessional patients with a corresponding premorbid obsessional makeup represent a small and not necessarily typical segment of individuals with obsessive–compulsive personalities. Clearly there is no necessary one-to-one relationship between obsessional personality and obsessional neurosis, despite the occasional finding that more obsessive–compulsive neurotics than would be expected by chance show evidence of a premorbid obsessional personality.

Several studies have been specifically concerned with the relationship between obsessional traits and the personality dimension of neuroticism. The findings of factor analytic studies such as those of Sandler and Hazari suggest that obsessional traits may relate inversely to neuroticism, whereas obsessional symptoms may relate positively to measures of neuroticism, maladjustment, and emotional instability. With one exception (Orme, 1965), the few studies that have addressed this issue report these relationships to exist (Kline, 1968; Meares, 1971; Paykel & Prusoff, 1973). Kline (1967) factor analyzed the Sandler-Hazari Scale (1960), the Beloff Anal Test (1957), and the MMPI, using the responses of a normal sample of 93 college students. Three relevant factors emerged: general emotional instability, a factor of obsessional character traits, and a factor of so-

cial introversion. Neither the Beloff nor the Sandler-Hazari measure (both measuring obsessional character traits) loaded highly on the emotional instability factor, while the Sandler-Hazari measure of obsessional symptoms loaded highly on both the social introversion and emotional instability factors. In a subsequent study, Kline (1968) factor analyzed the MMPI, the Beloff Anal Test, the Sandler-Hazari Scale, and his newly devised anal scale (AI3), a measure of obsessional traits, and discovered that his measure also did not load on the emotional instability factor that runs through the clinical scales of the MMPI. Meares, using a sample of 32 patients with spasmodic torticollis, found a moderate positive correlation ($r = .6$, $p <$ .001) between a measure of neuroticism (the Eysenck Personality Inventory) and the obsessional symptoms section of the Sandler-Hazari Scale. Obsessional traits also measured by the Sandler-Hazari Scale were negatively related to the Eysenck Personality Inventory Neuroticism scale ($r = -.31$). Orme (1965) reported that obsessional character traits correlated moderately with a measure of emotional instability, Cattell's (Cattell & Eber, 1957) 13-item 'O' Factor Scale, in samples of normals and obsessional neurotics, but, as Paykel and Prusoff pointed out, Orme's measure of traits was derived from Sandler and Hazari's second dimension of ego-alien phenomena and relates more to obsessional symptoms than to obsessional traits. Paykel and Prusoff reported additional evidence that neuroticism, as measured by the Maudsley Personality Inventory, relates inversely to obsessional traits, as measured by the Lazare-Klerman Trait Scales ($r = -.23$, $p < .05$), in a sample of 131 recovered depressed male and female psychiatric patients. In a recent study, however, Pollak (1978), using the Lazare-Klerman Trait Scales as a measure of obsessive personality, found in a sample of graduate students ($N = 114$) that obsessive personality correlated negatively with several self-actualization variables of the Personal Orientation Inventory (Shostrom, 1966; r ranged from $-.16$ to $-.40$). If one views this inventory as a measure of optimal emotional functioning or positive mental health, then the inverse relationships found at least suggest that obsessive personality may reflect a somewhat immature, if not neurotic, character structure.

In summary, with some notable exceptions, studies indicate significant positive relationships between measures of obsessional neurosis and measures of emotional instability and significant negative relationships between obsessional trait measures and emotional instability (Slade, 1974).

Obsessive–Compulsive Personality and Introversion–Extraversion

According to the personality model of Eysenck (1947, 1959, 1960), two orthogonal dimensions are used to account for the psychoneuroses, namely, neuroticism and extraversion–introversion. Hysterical character disorders are viewed, for example, as disturbances of the neurotic extravert, whereas obsessive–compulsive disorders are classified as disorders of the neurotic introvert. Thus, according to this paradigm, obsessive–compulsive and hysterical patients are conceptualized as occupying opposite ends of a neurotic, introversion–extraversion continuum.

C. M. Rosenberg (1967) found, in a sample of obsessional neurotics, significantly lower than average scores both on the Extraversion scale of the Maudsley Personality Inventory and on the second-order extraversion factor of the Sixteen Personality Factor Questionnaire (Cattell & Eber, 1957). Several other studies (e.g., Barret, Caldbeck-Meenan, & White, 1966; Caine & Hope, 1964; Forbes, 1969; Foulds et al., 1965) have found sizable correlations in the .70 to .80 range between performance on the Hysteroid-Obsessoid Questionnaire (Caine & Hawkins, 1963) and performance on the Extraversion scale of the Maudsley Personality Inventory and the second-order factor Extraversion scale of Cattell's Sixteen Personality Factor Questionnaire in psychiatric and nonpsychiatric samples, with subjects classified as obsessoid consistently scoring significantly lower on the extraversion measures than subjects classified as hysteroid. The results of these studies suggest that obsessive and hysterical personalities can be conceptualized as opposite ex-

tremes on an introversion–extraversion continuum, with obsessional personality highly related to introversion and hysterical personality to extraversion.

Paykel and Prusoff (1973), however, could not find any relationship between obsessional traits, as measured by the Lazare-Klerman Trait Scales, and the introversion–extraversion dimension, as measured by the Extraversion scale of the Maudsley Personality Inventory, in a sample of recovered depressed patients ($N = 131$). Moreover, in some earlier factor analytic research cited above, Kline (1967) found that obsessional character traits measured by both the Sandler-Hazari Scale of obsessional traits and symptoms and the Beloff Anal Test did not load highly on a social-introversion factor, whereas the Sandler-Hazari measure of obsessional symptoms, with a loading of .512, did.

It is interesting that when measured by the Hysteroid-Obsessoid Questionnaire, obsessive–compulsive personality appears positively related to introversion, but that when measured with other instruments like the Lazare-Klerman Trait Scales, it seems independent of the introversion–extraversion personality dimension.

Obsessive–Compulsive Personality and Response to Experimental Tasks

A number of studies have attempted to discover whether obsessive–compulsive personalities respond in experimental situations in ways congruent with predictions made from theory and clinical observation. For example, is there empirical evidence for the notion that obsessive individuals crave order and structure and strive to be methodical and efficient in their actions?

B. G. Rosenberg (1953) compared the performance of psychotherapy patients with pronounced obsessive–compulsive tendencies with a normal control group on a visual memory task that involved choosing from a multiple-choice format the ambiguous design previously seen in tachistoscopic presentation. The alternative choices varied in terms of degree of symmetry, and as expected, he found that obsessive–compulsive subjects tended to favor the more symmetrical choices. This was interpreted as reflecting a particular need to impose order, uniformity, and congruity on visual perception. It is an interesting finding that has never been directly cross-validated. Studies of a somewhat related nature, however, that used measures such as the Breskin nonverbal test of rigidity to explore correlates of perceptual rigidity have been reported (e.g., Breskin, 1968; Breskin, Gorman, & Hochman, 1970; Primavera, Simon, & Hochman, 1974).

In a more recent study that used a sample of 40 college men, Rosenwald (1972) found significant relationships between a measure of anxieties reflective of anal concerns and time spent bringing order to a disorderly situation, that is, straightening up of a pile of scattered magazines. No relationship, however, was found between time spent reorganizing the magazines and another questionnaire measure that specifically concerned anxiety about dealing with dirt. No relationship could be found, as well, between time spent on the reorganization task and efficiency in identifying geometric forms with their hands while the objects were immersed in a dirty, malodorous, feces-like medium. Poor or inefficient performance on this latter task was interpreted as indicative of weak defenses against anal impulses.

There are a few studies to date that have investigated differences in degree of anal orientation as a function of occupational choice. Would, for example, more obsessional individuals be found in occupational pursuits that emphasize being orderly and methodical? Using a Q-sort technique, Weinstein (1953) found, as predicted, that engineering students were more anal retentive than law or social work students. Using projective measures like the Rorschach test and the Bender-Gestalt test, Segal (1961) found partial support for his hypothesis that accounting students would demonstrate a greater degree of anal orientation than would creative writing students. He found, as expected, that the accounting group was less tolerant of ambiguity, more restrained in expression of hostile affect, and generally more emotionally controlled. No differences were found between the groups, though, in their use of compulsive defenses

and conformity to social expectations. Consistent with her predictions, Schlesinger (1963) found that accounting and engineering students exhibited a significantly greater anal orientation than did educational psychology students. White (1963), in a study of experienced clerical bank personnel, found an intense dislike of dirt and disorder not found to the same degree in a control group sample.

Although these studies of vocational activity in the main support psychoanalytic theorizing and clinical description insofar as they suggest positive relationships between obsessional characteristics and involvement in the more compulsive kinds of vocational pursuits, the findings would be strengthened if comparable results were to be found in studies that include only individuals actually practicing in different professions. With the exception of the study by White, findings have been based solely on responses of students and not practitioners.

A few studies have explored relationships between anal characteristics and verbal recall ability, a dependent variable that appears to bear some relation to both the presumed orderliness and retentiveness of obsessive–compulsive individuals. Adelson and Redmond (1958) hypothesized that anal retentive individuals should possess methodical and efficient ways to process and retain information. Using the performance of a sample of 61 college women on the Blacky Pictures (Blum, 1949), they found, as predicted, that anal retentive subjects showed significantly greater ability for immediate and delayed recall of prose passages than did anal expulsive subjects or subjects classified as neutral.

Pedersen and Marlowe (1950), in an earlier study, were unable to duplicate these findings using a male sample, and Marcus (1963), using the performance of female college students on the Blacky Pictures, found anal retentives to be superior to anal expulsives only with delayed as opposed to immediate recall of words. D. F. Fisher and Keen (1972) used the Blacky Pictures with a group of army men and found no significant relationships between the anality measures of retentiveness and expulsiveness and measures of recall of verbal material. As S. Fisher and Greenberg (1977) pointed out, results are mixed, with findings more congruent with theory in studies that used female subjects.

Several studies have investigated the presumed tendency of obsessive–compulsive personalities to be obstinate and negativistic. In a series of studies, it was found that, unlike "oral" subjects, "anal" subjects were extremely difficult to verbally condition using positive reinforcement (Cooperman & Child, 1971; Noblin, Timmons, & Kael, 1966; Timmons & Noblin, 1963). In a similar kind of investigation, Tribich and Messer (1974) found that oral subjects reported an amount of light movement similar to that reported by an authority figure when viewing the autokinetic phenomenon in their presence, whereas anal subjects tended to respond in opposition to the authority. In all four of the experimental studies that used the Blacky Pictures as a measure of orality and anality and that used college students as subjects, results were consistent with theory and the clinical impression that anal characters are often negativistic and resistant to control from authority figures.

The results of other studies suggest positive relationships between measures of anal character traits and such predicted oppositional behavioral features as nonacquiescent response set (Couch & Keniston, 1960), intense dislike for a task engaged in under conditions of forced compliance (Bishop, 1967), and resistance to attitude change (Rosenwald, 1972).

In obsessional personalities the trait of obstinacy is often linked with rigid, defiant, and hostile attitudes. In fact, the presumed rigidity of the obsessive–compulsive is thought to manifest itself in most, if not all, aspects of the individual's behavior, for example, in thought processes, perceptual style, verbal expression, motor activity, and so on (e.g., Reich, 1949; Shapiro, 1965). Authoritarianism has traditionally been linked in personality research literature to variables such as rigidity, low tolerance for ambiguity, and aggressive and hostile attitudes (e.g., Adorno, Frenkel-Brunswick, Levinson, & Sanford, 1950). Three studies that related obsessive–compulsive characteristics to rigid authoritarian beliefs and attitudes found positive relationships between the two, as might be

expected (Centers, 1969; Farber, 1955; Rogers & Wright, 1975). Farber found a correlation of .37 ($p < .01$) between the traits of orderliness, frugality, and obstinacy and what he termed political attitudes of *aggressive conventionality* (which emphasize strong antipathy to communism) in a fairly large sample of male and female college students ($N = 130$). Although Rabinowitz (1957) could not replicate Farber's results using a similar sample, some years later Centers (1969) found a relationship of comparable magnitude between a measure of anality and hard-line conservative attitudes on such issues as welfare and law and order in a cross-sectional sample of over 500 adults. Along similar lines, Rogers and Wright (1975) reported a sizable correlation of .62 ($p < .01$) between authoritarianism as measured by the California F Scale and obsessive–compulsiveness as measured by the Psychasthenia scale of the MMPI in a mixed sample of 38 undergraduates.

The character trait of obstinacy in obsessive–compulsive personalities has also been associated with conflictual and ambivalent attitudes toward the recognition and expression of hostile feelings. There are only a few studies that have experimentally explored this issue. In the study by Segal (1961), alluded to earlier, the presumably more anal student accountant group demonstrated more restraint in the expression of hostile affect on projective measures than did a group of creative writing students. Gordon (1966, 1967) related the nature and types of psychological interpretations made by clinical psychologists and clinical psychology trainees to the personality dimension of anality as measured by the Grygier Anality Scales (Grygier, 1956). Consistent with the point of view of Fenichel (1945) and Schafer (1954) that anal character types often lack confidence, are indecisive, sometimes demonstrate strong reaction formations against hostility, and tend toward generalization in their thinking, she found that high-anal clinicians had less confidence in their interpretations, made fewer specific predictions, and identified less psychopathology in the case and test material presented to them than did clinician groups designated as low anal or neutral on the basis of performance on the Grygier Anality Scales. In the aforementioned study by Rosenwald (1972), which employed both questionnaire and behavioral measures of anality, some evidence was found to support predicted relationships between anal character orientation and anxiety-ridden, conflictual, and ambivalent attitudes toward hostile and aggressive feelings and actions, as measured by questionnaires and responses to specific action-oriented tasks. The results overall were mixed, however, in relating the measures of anality to the measures of hostility and aggression. In support of theory, though, Rosenwald found that subjects high on two questionnaire measures of anal anxiety demonstrated more anxiety and were slower in performing a doll-destruction task than were subjects low on the anality measures.

With regard specifically to the anal feature of indecisiveness that was explored in Gordon's research, Rosenwald, Mendelsohn, Fontana, and Portz (1966) compared the performance of male college students on a task that involved identification of geometric forms with the hands under two conditions. In one condition, hands were placed in a feces-like medium; in the other, the geometric forms were handled in water. Inefficient or blocked performance under the more unpleasant conditions was construed as indicative of anally linked anxieties and was found to be positively related to indecisiveness, as defined by the amount of time subjects thought they needed to make the necessary perceptual estimates.

Empirical support for the presumed anal character trait of parsimony was sought in a few studies (Lerner, 1961; Noblin, 1962; G. M. Rapaport, 1955; Rosenwald, 1972). According to classical analytic formulations, money is equated in the unconscious with the excretory product, and activities that involve hoarding, collecting, and preserving objects, especially those symbolic of the excretory product and anal function, become paramount in the behavioral style of the anal character, as a sublimation of the infantile wish to hold and retain feces.

In the study by Noblin, 60 hospitalized psychiatric patients placed into anal or oral groupings on the basis of responses to the

Blacky Pictures and on the basis of psychoanalytically formulated diagnoses were differentially rewarded by food or pennies in a verbal conditioning paradigm aimed at increasing the use of personal pronouns in constructing sentences. Anal subjects were found to be best motivated by the money reinforcer, whereas oral subjects were differentially responsive to the food reinforcer, as theory would predict. Using a sample of teenage boys ($N = 30$), Lerner (1961) reported that serious stamp collectors were either significantly more sensitive or selectively insensitive to anally tinged words than to neutral words presented on an audiotape in comparison to a matched group of boys with no collecting interests. Rosenwald (1972) found some evidence that degree of anal orientation was related to the wagering of less money in a gambling situation, but the relationship reported was only found with one of two questionnaire measures of anality and was not shown when the hand-immersion behavioral efficiency task, alluded to above, was employed as an index of anality. In an earlier study, Rapaport (1955) failed to find significant relationships between anality and degree of concern with money on the Thematic Apperception Test.

The character trait of parsimony should naturally carry over and be reflected in how the obsessive–compulsive individual approaches and manages time. Some early analytic formulations (e.g., Jones, 1918/1961) postulated that time also is an unconscious equivalent of the fecal product. Therefore, by virtue of their predominant anal fixations, obsessional personalities are considered to be particularly sensitive about wasting time and having to spend time against their will; they insist on being masters of their own time.

Three studies to date have investigated relationships between anal character traits and attitudes toward time (Campos, 1966; Gorman & Katz, 1971; Pettit, 1969). Campos found, in a sample of 100 male undergraduates, a positive relationship between anal retentive traits and the tendency to overestimate intervals of time. This finding is consistent with the view that time is overestimated precisely because it is something of special value to be retained if at all possible. Also reported was a positive relationship between degree of anality and the tendency to use time in a niggardly, thrifty, and cautious manner. In the study by Pettit, sizable positive correlations (.5 to .65; $p < .001$) were found between the Grygier Anality Scales (Grygier, 1956) and a *composite anality scale* devised for the study and a time questionnaire designed to measure the importance of time to the individual in ordering and controlling experience. Subjects used were 91 undergraduates. No significant sex differences were found. Gorman and Katz (1971) sought to replicate and extend Pettit's findings, using another sample of undergraduates ($N = 110$). They administered Pettit's time scale and composite anality scale, and in addition subjects completed four time scales that measure various time attitudes (Calabresi & Cohen, 1968). The time-anxiety scale measures uncomfortable feelings and thoughts about the future and a frustrated longing for the past. The time-submissiveness measure reflects dutiful and conforming attitudes toward time. Analysis of the data confirmed Pettit's findings of a strong relationship between anality and time attitudes, but only for specific aspects of time attitudes. Significant relationships were found between all time measures and the anality measure, except for a nonsignificant and quite low correlation ($r = .14$) between anality and time possessiveness. A correlation of greater magnitude was expected, given the presumed strong retentive orientation of obsessive individuals. The overall pattern of the results did suggest that the constellations of time attitudes and anal character traits might be more fruitfully conceptualized under the rubric of *rigidity* or *obsessive–compulsive character style,* a category which does not reflect psychopathological behavior, but simply reflects a distinct personality style.

Directions for Further Research

More study of the perceptual correlates of obsessive–compulsive personality is urged. Although there have been some intriguing findings (e.g., B. G. Rosenberg, 1953), very little research has been conducted in this

area to date. What, for example, would the relationship be between obsessive–compulsive personality and the field dependence–independence construct of Witkin and his associates (Witkin et al., 1954).

More research on the relationship of obsessive–compulsive personality to measures of aesthetic sensitivity and indices of creative thinking in verbal and nonverbal mediums is also recommended.

The particular kinds of meanings ascribed by obsessive–compulsive personalities to critical life situations and tasks, for example, vocational choice, marriage, death and dying, and so on, would also be an interesting area to explore. Is there, for example, a difference in the way obsessional personalities conceptualize or personify death and dying, as opposed to the perceptions of individuals considerably less obsessional in their orientation to life or of individuals with fundamentally different personality styles, for instance, those designated as oral, hysterical, impulsive, and so forth? If differences are found, are they, in fact, consistent with clinical observation and predictions from theory? A study of meaning would begin to focus more on how obsessional personalities experience the world and might produce empirical data that would help to better evaluate the existential, phenomenological points of view on obsessional personality style (e.g., Becker, 1974; M. H. Miller & Chotlos, 1960; Strauss, 1966).

Conclusions and Summary

One of the difficulties in attempting to evaluate the findings of the empirically based research is that a diverse number of specific measures and types of measurement approaches have been employed. Many of the indices of anality and obsessive–compulsive characteristics that have been used possess questionable psychometric adequacy. For example, for a time, particularly in the 1950s and 1960s, the Blacky Pictures (Blum, 1949) was often used as a measure of anality; but the Blacky Pictures is a projective test that carries with it all of the problems of standardization, reliability, and validity that have come to be associated with the use of projective tests in personality assessment and research (e.g., Anastasi, 1968).

In addition, there have been few attempts to cross-validate some of the more intriguing findings, and some of the attempts to replicate have resulted in inconsistent findings. Moreover, only a few researchers have devoted themselves to repeated and in-depth treatment of a particular area of study in an attempt to refine measurement techniques and more closely study relationships suggested by theory or prior experimentation. On the basis of this review of the empirical literature on obsessive–compulsive personality, the following conclusions appear to be warranted.

1. Obsessive–compulsive personality, as a cluster of traits, appears to possess considerable empirical validity and to fairly closely adhere to clinical descriptions and predictions. This is true despite the fact that an array of measurement approaches and specific measurement instruments have been employed in an attempt to correlate measures of anality with various behavioral indices.

2. Obsessive–compulsive personality can be statistically differentiated from obsessive–compulsive symptomatology through factor analysis.

3. In most instances obsessive–compulsive personality does not appear to be positively related to measures of neuroticism, whereas obsessional symptoms do; however, findings are somewhat inconsistent on this issue.

4. Obsessive–compulsive personality may be independent of an introversion–extraversion classification scheme, but more study with diverse measures of obsessive–compulsive personality is needed to help clarify this issue.

5. Obsessive–compulsive traits appear to be normally distributed.

6. There appears to be little evidence in favor of classical psychoanalytic theories about the psychogenesis of obsessive–compulsive personality. Overall, there is yet no strong empirical support for any etiologic explanation. There are, though, suggestions in clinical observation and in some statistically based research that obsessive–compulsive individuals often are the progeny of obsessive–compulsive parents and that obsessional or anal character structure develops, at least in part, from early learning, but not necessarily

exclusively out of the toilet training period per se. Rigid, compulsive parenting, however, may very well be maximal before and during the time that sphincter control is still in the process of development.

Ridge Regression: Bonanza or Beguilement?

William W. Rozeboom
University of Alberta, Edmonton, Canada

Ridge regression is an intriguing new toy for statistical estimation theory. But it is just that—a *toy* which may someday evolve into a useful if limited tool but is still too fragile to do real work. Specifically, ridge regression can indeed improve upon the accuracy of traditional estimates of regression parameters if background circumstances are right. But if they are not right—and how to diagnose this remains obscure—ridge regression incurs a loss of estimational accuracy.

Estimation of regression coefficients by ridge regression (Price, 1977) as a way to reduce the very large sampling uncertainty that invests classically estimated regression coefficients when the estimation sample's predictor distribution approaches multicollinearity is an exciting new methodological prospect. But exciting new prospects have a regrettable proclivity for promise without fulfillment—which is to say, more gently, that exploration usually comes up empty despite our need to keep looking if we are ever to find any new goodies at all—and ridge regression is no great exception to this rule. As will be acknowledged, the concept behind ridge regression has some merit; but its application to practical problems of predictor multicollinearity is both conceptually misleading and of uncertain practical value.

Preliminaries

It is misleading to characterize ridge regression as a partial solution to predictor multicollinearity for the simple reason that the degree to which the accuracy of ridge regression may or may not improve upon that of the classical procedure (called *ordinary least squares* or OLS by Price) for estimating predictor coefficients has nothing to do with the severity of predictor intercorrelations and is in principle equally helpful—or unhelpful—when the predictors are fully independent of one another. This is because (a) our predictor variables $X = \langle x_1, \ldots, x_m \rangle$ can always be rotated into an orthogonal basis $F = \langle f_1, \ldots, f_m \rangle$ for X space by a linear transformation $F = X\mathbf{W}$, in which $\mathbf{W}$ is an $m \times m$ matrix of rotation coefficients; (b) the column vectors $\mathbf{b}_X$ and $\mathbf{b}_F$ of the criterion variable's true regression coefficients on X and F, respectively, stand in relation $\mathbf{b}_X = \mathbf{W}\mathbf{b}_F$; (c) almost any method for estimating $\mathbf{b}_X$, OLS, and its ridge-regression extension in particular can be construed as a method that first estimates $\mathbf{b}_F$ as $\hat{\mathbf{b}}_F$ and then converts the latter into its estimate $\hat{\mathbf{b}}_X$ of $\mathbf{b}_X$ by transformation $\hat{\mathbf{b}}_X = \mathbf{W}\hat{\mathbf{b}}_F$; and (d) for OLS and ridge regression, when $f_1, \ldots, f_m$ are orthogonal, the expected squared error $\mathrm{Exp}[(\hat{b}_{X_i} - b_{X_i})^2]$ of the ith term of $\hat{\mathbf{b}}_X$ is a weighted sum of the expected squared errors of $\hat{b}_{F1}, \ldots, \hat{b}_{Fm}$, the weight of $\mathrm{Exp}[(\hat{b}_{Fj} - b_{Fj})^2]$ being the square of the ijth element of $\mathbf{W}$.[1] Point d explains why predictor near-multicollinearity can ravage the accuracy of $\hat{\mathbf{b}}_X$, though I defer details until

[1] I have slid quickly by a number of technical points here. For one, we assume that none of the predictors is exactly a linear function of the others in the sample, albeit this degeneracy can be approached as closely as we please. The sampling model envisioned here and later is the one with fixed predictor covariances, that is, we consider the sampling distribution of $\mathbf{b}$ under repeated sampling with sample size and the predictor covariances held constant at the values found in our actual sample. And when ridge regression's $\mathbf{K}$-matrix parameter is taken to be a sample-dependent random variable rather than a constant, it is possible for point d to be true of ridge regression only approximately, depending on the details of $\mathbf{K}$'s selection.

later. It also shows that the expected squared error of $\hat{b}_{X_i}$ can be less for ridge regression than for OLS only when this is also true for some of the $\hat{b}_{F_j}$ for orthogonal predictors $f_1, \ldots, f_m$.

The Nature of Ridge Regression

Estimating the simultaneous regression of criterion variable y on several orthogonal predictors is equivalent, that is, yields the same numerical results, for both OLS and ridge regression to estimating y's regression on each predictor separately.[2] Let us, therefore, analyze the nature of ridge regression for a single predictor x.

According to the standard sampling-theoretic regression model, $y = a + bx + e$, in which a and b are scalar constants (a being of no further interest here) and e is a residual variable, statistically independent of x, whose mean and variance under repeated sampling are respectively zero and an unknown quantity σ_e^2. Let σ_x^2, c_{yx}, and c_{ex} be, respectively, the variance of x, the covariance of y with x, and the covariance of e with x in the observed size-N sample from which we hope to estimate b. (We assume $\sigma_x^2 > 0$; otherwise b is not well-defined.) Then $c_{yx} = b\sigma_x^2 + c_{ex}$; while given a fixed N and σ_x^2 (see Footnote 1) and fully random sampling on e, it is easy to prove that

$$\mathrm{Exp}(c_{ex}) = 0, \quad \mathrm{Exp}(c_{yx}) = b\sigma_x^2,$$

and

$$\mathrm{Exp}(c_{ex}^2) = N^{-1}\sigma_e^2\sigma_x^2.$$

For any estimate $\hat{b}$ of b, let $S(\hat{b})$ be the expected squared error of $\hat{b}$, that is,

$$S(\hat{b}) =_{\mathrm{def}} \mathrm{Exp}[(\hat{b} - b)^2],$$

while henceforth $\dot{b}$ and $\tilde{b}$ are specifically b's OLS and ridge-regression estimates, respectively. Classically, OLS estimate $\dot{b}$ is defined to minimize $S(\dot{b})$ under the constraint that $\dot{b}$ is unbiased, leading to the computational formula $\dot{b} = c_{yx}/\sigma_x^2$. It follows that

$$\dot{b} = (b\sigma_x^2 + c_{ex})/\sigma_x^2 = b + c_{ex}/\sigma_x^2,$$

whence

$$\mathrm{Exp}(\dot{b}) = b$$

and

$$S(\dot{b}) =_{\mathrm{def}} \mathrm{Exp}[(\dot{b} - b)^2] = \mathrm{Exp}(c_{ex}^2)/\sigma_x^2 = \sigma_e^2/N\sigma_x^2,$$

which says inter alia that $\dot{b}$ is unbiased and that its expected squared error is independent of the parameter being estimated. $S(\dot{b})$ is not, however, independent of the predictor variable's variance—nor can it be for any estimate of b, insomuch as b itself is dependent on σ_x^2. For if x is linearly rescaled to shift its standard deviation from σ_x to $\sigma_{x^*} = s\sigma_x$, b is correspondingly rescaled to $b^* = s^{-1}b$, leaving $b^2\sigma_x^2$ (the amount of y variance linearly accounted for by x) invariant. But as b is multiplicatively adjusted by scaling factors, so of necessity is any estimate $\hat{b}$ of b together with its expected squared error. In particular, $S(\hat{b})$ can be made arbitrarily large by making σ_x sufficiently small. The ratio of $S(\hat{b})$ to b^2, however, is generally independent of the predictor scale. For OLS estimation in particular,

$$S(\dot{b})/b^2 = \sigma_e^2/Nb^2\sigma_x^2 = (1 - \rho_{yx}^2)/N\rho_{yx}^2,$$

where ρ_{yx} is the correlation between y and x in the population sampled[3] and is approximated (with a positive bias that vanishes with increasing N) by the sample correlation.

Ridge regression seemingly aspires to improve upon OLS estimation by correcting for the very large $S(\dot{b})$ that accompanies very small σ_x^2. Specifically, the ridge-regression estimate of b is $\tilde{b} = c_{yx}/(\sigma_x^2 + k)$, in which k is a small positive quantity whose numerical value is the task of ridge-regression theory to provide. (More generally, for multiple pre-

---

[2] More precisely, this is true of orthogonal predictors' OLS-estimated regression coefficients. The estimated uncertainty associated with the estimate of each b_{X_i} is a mildly increasing function of the number of additional predictors, insomuch as estimating coefficients also for the latter incurs a degrees-of-freedom loss from the total sample size.

[3] More precisely, ρ_{yx} is the correlation between y and x in a very large population that randomly samples e while having the same predictor variance as the observed sample (see Footnote 1). Also, when x is only one of m orthogonal predictors, ρ_{yx} is not the zero-order correlation between y and x, but is their partial correlation after the other predictors have been partialed out.

dictors, ridge regression alters some or all roots of the predictor covariance matrix by small increments that in the method's simplest version are the same for all roots.) However, we have just noted that σ_x^2 can be set at any stipulated positive value by choice of predictor scale; hence if $S(\tilde{b})$ can be less than $S(\dot{b})$ for some k when σ_x^2 is very small, the same degree of improvement must be possible when σ_x^2 is arbitrarily large.

The essential character of ridge regression, and its relation to OLS estimation, is evident in the relation

$$\tilde{b} = c_{yx}/(\sigma_x^2 + k)$$
$$= (c_{yx}/\sigma_x^2)[\sigma_x^2/(\sigma_x^2 + k)] = \dot{b}h, \quad (1)$$

where $h =_{\text{def}} (1 + k/\sigma_x^2)^{-1}$ and $h < 1$ if $k > 0$. Thus $\tilde{b}$ is simply an attenuation of $\dot{b}$ by a to-be-selected shrinkage factor h (cf. Mayer & Wilke, 1973). Since

$$\tilde{b} - b = \dot{b}h - b = (\dot{b} - b)h + b(h - 1),$$

or

$$(\tilde{b} - b)^2 = (\dot{b} - b)^2h^2 + 2(\dot{b} - b)bh(h - 1) + b^2(h - 1)^2,$$

the expected squared error of b conditional on a fixed (i.e., sample-independent) value of h is

$$S[\tilde{b}_{(h)}] = h^2S(\dot{b}) + b^2(h - 1)^2$$
$$= S(\dot{b})\cdot[(1 - h_0)^{-1}(h - h_0)^2 + h_0], \quad (2)$$

where

$$h_0 =_{\text{def}} [1 + S(\dot{b})/b^2]^{-1}$$
$$= [1+(1 - \rho_{yx}^2)/N\rho_{yx}^2]^{-1}$$
$$= N\rho_{yx}^2/[(N - 1)\rho_{yx}^2 + 1]. \quad (3)$$

The choice of h that minimizes $S[\tilde{b}_{(h)}]$ is thus $h = h_0$, given which the inaccuracy of b compared with that of OLS estimate $\dot{b}$ is $S[\tilde{b}_{(h_0)}]/S(\dot{b}) = h_0$. Even if h is chosen non-optimally, moreover, $S[\tilde{b}_{(h)}]$ is still less than $S(\dot{b})$ if h differs from h_0 by less than $1 - h_0$. Hence if there is a practical way to choose h in this interval with suitably high probability, ridge regression will indeed be more accurate than OLS estimation even if the improvement cannot amount to much unless h_0 is appreciably less than unity.

Before considering whether this prospect can be realized, however, observe that nothing in Equations 1, 2, and 3, save replacement of $S(\dot{b})/b^2$ by its analysis in terms of ρ_{yx}, is specific to estimation of regression coefficients. The term $\dot{b}$ can be any unbiased estimator from which adjusted estimator $\tilde{b} = \dot{b}h$ is obtained by an attenuation factor h. If this correction procedure can be made to work for estimation of regression coefficients, then we must anticipate that it may also be workable for many other classic unbiased estimators, starting with the sample mean as an unbiased estimate of the population mean. Either the logic of ridge regression calls for wholesale reappraisal of all established statistical estimation procedures or there is something impractically fragile about its applicability.

There is good reason to suspect the latter. For, any procedure that endeavors to select a value of h as close to h_0 as possible is in effect a procedure for estimating h_0; and since h_0 is so importantly a function of b, this is tantamount to deriving $\hat{h}_0$ from an estimate of b, the very parameter that is at issue in the first place. Although ridge regression's logic is thus circular, the circle is not necessarily vicious. Conceivably an iterative procedure, in which h_0 is estimated from a prior estimate of b (more precisely of $S(\dot{b})/b^2$) and the latter is then revised in light of $\hat{h}_0$, may bring off convergence to a more accurate estimate of b than the one with which the iteration begins. But success at this will clearly be a delicate business, critically dependent on both the sampling details of the particular parameters at issue and an astute choice of input to the iteration.

Equation 2 does not properly characterize any version of ridge regression that selects h in light of sample data, insomuch as h now has a sampling distribution that is not independent of $\dot{b}$. Instead, by some routine algebra applied to the analysis of $(\tilde{b} - b)^2$ noted prior to Equation 2, we find that

$$S(\tilde{b}) = S(\dot{b})\{(1 - h_0)^{-1} \times \text{Exp}[(h - h_0)^2] + h_0\} + C \quad (4)$$

where

$$C =_{\text{def}} \text{cov}(\dot{b}^2, h^2) + 2b\,\text{cov}[\dot{b}, h(h - 1)],$$

while h_0 is still defined by Equation 3 and cov designates sampling covariance. The quantity

$\operatorname{Exp}[(h - h_0)^2]$ is just the expected squared error $S(\hat{h}_0)$ of h construed as an estimate $\hat{h}_0$ of h_0, so Equation 4 can be rewritten as

$$S(\tilde{b})/S(\dot{b}) = h_0 + (1 - h_0)^{-1}S(\hat{h}_0) + C/S(\dot{b}). \quad (5)$$

Terms $S(\hat{h}_0)$ and $C/S(\dot{b})$ in Equation 5 can be analyzed further, but there is little present point in doing so except to claim without proof that all terms in Equation 5 are nonnegative unless ρ_{yx}^2 is less than N^{-1}, in which case it is possible for $C/S(\dot{b})$ to assume a small negative value. The present import of Equation 5 is simply that ridge regression can degrade estimational accuracy as well as enhance it. For regardless of how tiny h_0 may be, $S(\tilde{b})$ will be larger than $S(\dot{b})$ unless $S(\hat{h}_0)$ is sufficiently small. Since the sampling distribution of h $(=\hat{h}_0)$ under any specific method H for generating h from the sample data will be dependent on N and ρ_{yx}^2, one must anticipate that even if $S(\tilde{b})$ is less than $S(\dot{b})$ under some values of these parameters, the superiority order will be reversed in other regions of $\langle N, \rho_{yx}^2\rangle$. But if ridge-regression variant H does not dominate OLS over the entirety of parameter space—and it appears exceedingly unlikely that any choice of H can—then it is irresponsible to advocate and foolish to use H in preference to OLS unless we know what the regions of $\langle N, \rho_{yx}^2\rangle$ space are in which $S(\tilde{b})/S(\dot{b})$ is, respectively, appreciably less and appreciably greater than unity, as well as how large the difference from unity in each region tends to be. Only then will we be positioned to make rational judgments about which method, OLS or ridge-regression variant H, is most plausibly the more efficient for the particular application at hand. (In principle, choice of an estimator should be a complex process that involves prior credibilities and decision-theoretic utilities as well as sampling probabilities. But determining the relevant sampling distributions conditional on the relevant parameters is not merely an essential step in the decision process; it is the one step that we can actually execute in practice without flagrant appeal to vague and probably idiosyncratic intuitions.)

Insomuch as any choice of shrinkage parameter h $(=\hat{h}_0)$ may be taken via Equation 3 to define an estimate $\hat{\rho}_{yx}^2$ of correlation parameter ρ_{yx}^2 (i.e., one replaces h_0 by h, ρ_{yx}^2 by $\hat{\rho}_{yx}^2$, and solves for the latter), whereas conversely any estimate of ρ_{yx}^2 can be converted by Equation 3 into an estimate of h_0, each variant H of single-predictor ridge regression is grounded at least implicitly on some technique for estimating ρ_{yx}^2 without benefit of a prior ridge-regression estimate of b. (Even when ridge regression seeks to refine its solution by iteratively alternating between estimation of ρ_{yx}^2 and of b, there must always be a starting $\hat{\rho}_{yx}^2$.) It is not clear that there are many cogent ways to do this; in fact, there is probably only one that can be considered operationally preferable at this time, namely, the classic bias-corrected OLS estimate (Wherry formula)

$$\dot{\rho}_{yx}^2 =_{\text{def}} \begin{cases} 1 - (N-1)(N-2)^{-1}(1 - r_{yx}^2) & \text{if greater than 0,} \\ 0 & \text{otherwise,} \end{cases}$$

in which r_{yx} is the observed sample correlation.[4] [Note that when $\rho_{yx} \neq 0$, $\dot{\rho}_{yx}^2$ is always less than r_{yx}^2 and becomes zero when $r_{yx}^2 \leq (N-1)^{-1}$.] Let $\tilde{b}^*$ be the b estimate computed by the variant H^* of ridge regression that derives h via Equation 3 from ρ_{yx}^2 estimate $\dot{\rho}_{yx}^2$. I now submit as a working hypothesis that under almost any parameter point $\langle N, \rho_{yx}^2\rangle$, if $S(\tilde{b}^*) \geq S(\dot{b})$, then also $S(\tilde{b}) \geq S(\dot{b})$ for any variant of ridge regression other than H^*. That is, I suggest that the region of parameter space in which some variant of ridge regression is superior to OLS is roughly included in the region of superiority for ridge-regression variant H^*. (Arguments can be given to support this conjecture, but since they are inconclusive I forgo them here.) If so, study of $\tilde{b}^*$'s sampling behavior will reveal the conditions under which ridge regression can improve upon OLS.

Although it does not seem possible to derive an analytically exact value for $S(\tilde{b}^*)/S(\dot{b})$ given $\langle N, \rho_{yx}^2\rangle$, this quantity can be determined closely enough by Monte Carlo simulation. Table 1 reports such results for a rather broad spectrum of $\langle N, \rho_{yx}^2\rangle$ values,

[4] When x is only one of m orthogonal predictors, r_{yx} is the sample's partial correlation between x and y (see Footnote 3), and $N - 2$ in this formula for $\dot{\rho}_{yx}^2$ becomes $N - m - 1$.

Note. Approximate probabilities that the sample-computed estimate $\dot{\rho}^2$ of ρ^2 is zero are in parentheses. Each tabled entry is the mean of $(\tilde{b}_i^* - b_i)^2$ divided by the mean of $(\dot{b}_i - b_i)^2$, in a set of 1,000 samples (P_i) of size N and stipulated population parameter ρ^2. Each P_i was obtained by the following algorithm: (a) Generate N-termed vectors $\mathbf{x}_i$ and $\mathbf{e}_i$ by elementwise independent production from a random generator whose distribution is unit normal. (b) Compute the variance V_i of $\mathbf{x}_i$, determine $b_i = (b_i^2)^{\frac{1}{2}}$ by solving $\rho^2 = b_i^2 V_i/(b_i^2 V_i + 1)$, and derive $\mathbf{y}_i = b_i\mathbf{x}_i + \mathbf{e}_i$. (c) Compute ordinary least squares estimate $\dot{b}_i$ and ridge-regression estimate $\tilde{b}_i^*$ of b_i from sample vectors $\mathbf{x}_i$ and $\mathbf{y}_i$ by the appropriate formulas. Note that the sampling model for this simulation is random criterion residuals given a fixed predictor distribution.

together with the probability that $\dot{\rho}_{yx}^2 = 0$ at each parameter point. (Note that the table's rows are indexed by the product of N and ρ_{yx}^2 rather than by the latter alone). Estimator $\tilde{b}^*$ is more efficient than $\dot{b}$ so long as $\rho_{yx}^2 < N^{-1}$ and is substantially so when ρ_{yx}^2 is closer to zero than to N^{-1}. But $S(\tilde{b}^*)$ begins to exceed $S(\dot{b})$ when ρ_{yx}^2 becomes only fractionally greater than N^{-1}, reaching inefficiencies half again as large as those of OLS. Moreover, although $\tilde{b}^*$ returns essentially to parity with $\dot{b}$ as ρ_{yx}^2 becomes sufficiently large, the range of ρ_{yx}^2 values over which $\tilde{b}^*$ is appreciably inferior to $\dot{b}$ for any given N is much larger than its range of superiority.

Table 1 makes plain that $S(\tilde{b}^*)$ is less than $S(\dot{b})$ for just those combinations of N and ρ_{yx}^2 under which zero $\dot{\rho}_{yx}^2$ has rather high probability. Indeed, it is precisely this rounding of the bias-corrected r_{yx}^2 up to zero that makes $\tilde{b}^*$ superior to $\dot{b}$ in the $\rho_{yx}^2 < N^{-1}$ region. It is not so clear, however, that successful ridge regression depends on the zero bound on ρ_{yx}^2. Instead, what seems to be the fundamental nature of ridge regression, and more generally of any "shrinkage" adjustment of any sample-based estimator, can be insightfully idealized as follows: Given some function $\hat{\theta}$ of sample data construed to estimate a scalar population parameter θ, select for each sample size N some fixed bounded interval I_N of $\hat{\theta}$ values, define $\tilde{\theta}$ to be the sample function whose value respectively equals the midpoint θ_I of I_N or the value of $\hat{\theta}$ according to whether the latter is or is not in I_N, and consider the θ-estimation efficiency of $\tilde{\theta}$ versus $\hat{\theta}$ as a

function of θ with fixed N. It is not hard to see that so long as I_N is neither too wide nor too narrow and the sampling distributions of $\hat{\theta}$ have reasonably orthodox properties (notably, tailing off in both directions from a center in the vicinity of θ), $S(\bar{\theta})/S(\hat{\theta})$ has a minimum value less than unity at a value of θ near θ_I from which, as θ increases (or decreases), $S(\bar{\theta})/S(\hat{\theta})$ first increases to a maximum greater than unity and then subsides to an asymptotic value of unity. The details of this relative-inefficiency function are rather sensitive to the width of I_N; and one can seek a width that yields a useful θ region within which $S(\bar{\theta})/S(\hat{\theta})$ is appreciably less than unity while the degree to which $S(\bar{\theta})$ exceeds $S(\hat{\theta})$ elsewhere is not large enough to be a significant loss. How closely such an ideal choice of I_N can be attained in various particular cases I have no idea.

The simple model I have just described can obviously be generalized in various ways. For example, more than one shrinkage interval can be adopted simultaneously; the width and placement of I_N can be allowed to depend in part on sample properties additional to N; and shrinkage toward θ_I can be a graded function of the difference between $\hat{\theta}$ and θ_I rather than all or none according to whether $\hat{\theta}$ is in I_N. Even so, the all-or-none model makes clear the rationale of this approach. In particular, it removes the prima facie implausibility that the logic of ridge regression might apply with equal success to improving for example the OLS estimate of the population mean. For estimation of almost any statistic θ, what the generic shrinkage method can achieve by modifying a received θ-estimator $\hat{\theta}$ is a pocket of increased estimational accuracy (compared with the accuracy of $\hat{\theta}$) in the vicinity of one or more stipulated θ values θ_I at the price of decreased efficiency when θ's actual value lies elsewhere, the greatest losses occurring just outside of the region(s) of gain. Evidently, the occasions most appropriate for exploiting this technique are those in which our prior credibility distribution for θ is concentrated in the vicinity of θ_I.

Multicollinearity Revisited

If my analysis above is sound, it greatly clarifies ridge regression's potential value for the predictor multicollinearity problem. Returning to where the section entitled Preliminaries leaves off, let $f_1, \ldots, f_m$ be the (data space) "principal factors" of the X configuration, that is, f_i is the ith principal component of the predictor distribution rescaled to have unit variance. Then $X = F(\mathbf{D}_\lambda\mathbf{T})$ or $F = X(\mathbf{T}'\mathbf{D}_\lambda^{-1})$, in which rotation matrix $\mathbf{D}_\lambda\mathbf{T}$ is the product of an orthonormal matrix $\mathbf{T}$ with the diagonal matrix $\mathbf{D}_\lambda$ of roots of the X configuration's covariance matrix. It can be shown that $\lambda_m \leq \sigma_{x_i}^2(1 - R_i^2)$, in which R_i is the multiple correlation of any x_i in X with the other predictors and λ_m is the smallest predictor root; hence if any of the x_i are highly predictable from the rest, λ_m^{-1} will be very large. Moreover,

$$S(\hat{b}_{Xi}) = \sum_{j=1}^{m} t_{ij}^2\lambda_j^{-1}S(\hat{b}_{Fj}), \qquad (6)$$

where $\hat{b}_{Xi}$ ($\hat{b}_{Fi}$) is either the OLS or ridge-regression estimate of the ith coefficient in y's regression on X (F). Since

$$\sum_{i=1}^{m} t_{ij}^2 = \sum_{j=1}^{m} t_{ij}^2 = 1,$$

Equation 6 says that $S(\hat{b}_{Xi})$ is a weighted average of the $S(\hat{b}_{Fj})$ *after these have been inflated (or shrunk) by the associated* λ_j^{-1}; nor is there any tendency for the weights t_{ij}^2 to countervail that inflation, insomuch as the average t_{ij}^2 across $i = 1, \ldots, m$ is m^{-1}, the same for all j. The large uncertainty in the OLS estimate of b_{Xi} under predictor near-multicollinearity lies not in any special difficulty in estimating b_{Fj} when f_j's associated root is small—for $S(\hat{b}_{Fj})$ is the same for all j, namely, $N^{-1}\sigma_e^2$—but in the rotation from F to X, and is fully as troublesome for ridge regression as it is for OLS estimation.

Even so, there is a practical admonition for ridge regression in Equation 6. Let γ_{Fj} be the inefficiency ratio $\gamma_{Fj} =_{\text{def}} S(\bar{b}_{Fj})/S(\hat{b}_{Fj})$, and for simplicity assume—as will generally obtain closely enough when the predictors are nearly multicollinear—that for a given i, $t_{ij}^2\lambda_j^{-1}$ is much larger for those j in a subset J_i of indices $j = 1, \ldots, m$ than it is for the rest. Then $S(\bar{b}_{Xi})/S(\hat{b}_{Xi})$ is approximately equal to the average value of γ_{Fj} over just the j in J_i. (Although this is a considerable simplification

of the exact relationship, it fairly characterizes its essential nature, especially when the γ_{Fj} have a small coefficient of variation across J_i.) Given predictor near-multicollinearity, moreover, J_i will almost always comprise a subset of those j for which λ_j is very small. It follows that if ridge regression can substantially improve the estimation of regression coefficients for *some* of the predictor distribution's principal factors and can focus its prowess on those with the smallest associated roots, it may yet manage to provide succor specifically for the multicollinearity problem.

This hope is not entirely forlorn. Given fixed predictor scales, fixed regression coefficients, and fixed residual criterion variance, it is easily seen that the squared population correlation between y and any predictor x is an increasing function of σ_x^2 and, conversely, approaches zero as σ_x^2 approaches zero. Moreover, although the principal factors in Equation 6 have unit variances by scale stipulation, there is reason to suspect that very small predictor roots often symptomatize predictor configurations that, in an obscurely intuitive sense, allocate only diagnostically negligible variance to the dimensions of predictor space corresponding to these roots. It is impossible to be clear on this point without wallowing in a complicated, assumption-laden account of causal structure, scaling conventions, and the origins of predictor scores; but we can expect that some tendency exists—just how strong a one remains an important open question—for very small λ_j to be associated with especially small $\rho_{yf_j}{}^2$. And we have already seen that ridge regression's best chance to improve upon OLS is when $\rho_{yf_j}{}^2$ is *very* small. Unhappily, even when $\rho_{yf_j}{}^2$ is very small, if it is not small enough, $\tilde{b}_{Fj}$ will be *less* accurate than $\dot{b}_{Fj}$, and this loss will be amplified in $\tilde{b}_{Xi}$ by λ_j^{-1}.

If ridge regression is to be applied to highly intercorrelated predictors, one clear recommendation emerges. One should *not* routinely attenuate the OLS-estimated regression coefficients specifically for the predictors' principal factors (or principal components) with very small associated roots. Instead ridge regression should be applied only to those principal factors f_j whose (partial) squared correlation with the criterion can plausibly be inferred from the sample correlation and any other relevant information to be small enough for $S(\tilde{b}_{Fj}) < S(\dot{b}_{Fj})$. If the f_j that so qualify also correspond to very low λ_j, as seems not unlikely but still far from certain, then that same degree of increased efficiency—or loss thereof if we have misjudged—can be passed along to ridge-regression estimates of the b_{Xi}.

Conclusions

The import of my present argument is that we can expect to benefit from ridge regression—and otherwise to lose—only given special parametric circumstances whose presence in real-life applications cannot yet be reliably ascertained. Yet a number of Monte Carlo simulations in the ridge-regression literature (see especially Dempster, Schatzoff, & Wermuth, 1977, as well as earlier studies referenced by Price, 1977) have shown one or more variants of ridge regression to be impressively superior to OLS under the parameters tested. However, the design of these simulations—assigning population regression weights to multiple predictors also given rather high degrees of near-multicollinearity—does not permit easy comparison to Table 1; and there is no inconsistency between my present Monte Carlo conclusions and the published multivariate simulations if the manner in which these have been constructed produces parametric partial correlations between the criterion and the predictors' near-zero-root principal factors so small as to lie within the particular method's success region for the sample sizes tested. But if this is so—and it must be so if my preceding argument is not badly flawed—then the practical significance of these simulations remains severely problematic. They *may* exhibit a reliable tendency in all multivariate data arrays, real and artificial alike, for small-root principal factors to have vanishingly small correlations with an outside criterion. (If so, ridge regression can be operationally recommended just as soon as we determine how small a root is small enough.) But alternatively, they may well illustrate merely that artificial data arrays often approach ideal simplicities much more closely than do real data. Unless the *ways* in which multivariate distributions arise empirically are suitably reflected in simulation

studies, one must be exceedingly cautious in generalizing from one to the other.

I am prepared to argue that the only natural circumstances in which ridge regression can expect a reliable association between minuscule predictor roots and vanishing criterion correlations are roughly those in which the predictor variables are themselves causal sources of the criterion. In all other cases, the appropriate way to deal with intercorrelated predictors is through inferential factor analysis. But that is a story for another occasion. For now, the salient summary is that although ridge regression and other shrinkage techniques hold promise for a considerable diversity of specialized purposes, their employment also incurs a distinct risk of appreciable loss; and we still lack operationally effective criteria, or even a rudimentary theory thereof, for judging when the risk is worth taking. In particular, before extant variants of ridge regression are urged upon unwary statistical consumers, it is imperative that we acquire some knowledge about whatever relation may obtain in *empirical* data arrays between predictor roots and the criterion's correlations with the corresponding dimensions of predictor space.

For applied statistical estimation, ridge regression's day may come. But it has not come yet.

Call for Nominations

The APA Publications and Communications Board invites nominations for the editorship of *Psychological Bulletin* for the years 1981 through 1986. R. J. Herrnstein is the incumbent editor. The new editorial appointment will be made this year in order to provide continuity in publication of the journal. The editor-elect will start to receive manuscripts in 1980 to prepare for issues published in 1981, the first year of the new editorial term.

To nominate candidates, prepare a brief statement of one page or less in support of each nomination. Submit nominations no later than April 1, 1979, to Anita DeVivo, P&C Board Liaison, APA, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

Intellectual Functioning in Duchenne Muscular Dystrophy: A Review

Nicholas J. Karagan
Department of Pediatrics
University of Iowa

Duchenne muscular dystrophy has traditionally been thought to be a primary disease of muscle, but recently it has been suggested that it may be secondary to a neuronal defect or to a generalized disorder of protein synthesis and membrane. However, to date there is no proof to unequivocally support any of these theories. A higher incidence of mental retardation and decreased intellectual functioning has been reported in the medical literature for Duchenne muscular dystrophy patients than for normals or other control groups. Recently there has been strong evidence to suggest that verbal ability, as reflected by the Wechsler Intelligence Scale for Children Verbal scale IQ, may be more commonly and significantly impaired in Duchenne muscular dystrophy patients than is nonverbal ability, as reflected by the Performance scale IQ. This article presents a comprehensive review of intellectual functioning in Duchenne muscular dystropy. The intent is to provide a basis for future attempts to relate the intellectual deficit in Duchenne muscular dystrophy to neuropsychological and neurobiological parameters of the disease.

The muscular dystrophies are one class of inherited myopathies that are characterized by progressive muscular weakness and degeneration of muscle tissue without apparent cause in either the peripheral or central nervous system. In this regard they are distinguished from another class of myopathies, the spinal muscular atrophies, that involve progressive weakness and degeneration of muscle secondary to degeneration of anterior horn cells (Moosa, 1974). Duchenne muscular dystrophy has traditionally been considered a primary disease of muscle, but recently it has been suggested that it may be secondary to a neuronal defect (McComas, Sica, & Currie, 1970, 1971; Moosa, 1974) or to a generalized disorder of protein synthesis and membrane (Ionasescu, 1975). However, to date there is no proof to unequivocally support any of these theories.

Of the various types of muscular dystrophies, Duchenne or pseudohypertrophic muscular dystrophy is by far the most common, as well as the most rapidly progressive. Its incidence is 279 per 1,000,000 male births (Hanson & Zellweger, 1968). Death usually occurs from inanition or cardiopulmonary disease between 15 and 20 years of age. Usually, only males are affected by the disease, which is X-linked recessive. Thus, female carriers have the theoretical probability that 50% of their male offspring will be affected and that 50% of their female offspring will be carriers. However, about 30% of the affected males are the result of spontaneous mutation (Hanson & Zellweger, 1968). Duchenne muscular dystrophy does occur in rare instances in females, such as in Turner's syndrome (sex chromosomal complement XO) or in carriers in which the Lyon effect (Lyon, 1961, 1966; Murphy & Thompson, 1969) is thought to permit its clinical expression. Diagnosis of the disease is based

Figure 1. Functional classification of Duchenne muscular dystrophy. (From "Psychometric Studies in Muscular Dystrophy Type IIIa (Duchenne)" by H. Zellweger and J. W. Hanson *Developmental Medicine and Child Neurology*, 1967, 9, 576–581. Copyright 1967 by Spastics International Medical Publications. Reprinted by permission.)

on a positive family history, clinical symptoms, elevated serum creatine phosphokinase, electromyography, and ribosomal protein synthesis (determined from a muscle biopsy). Figure 1 summarizes the 10 stages of the disease, which are based on the ambulatory and transfer capabilities of the patient (Zellweger & Hanson, 1967). As can be seen, upper limb involvement progresses slowest, and finger dexterity is intact until the very latest stages, indicating that manual tasks can be accomplished without interference of the disease through Stage 5 and with minimal to moderate involvement through Stage 8.

A higher incidence of mental retardation and decreased intellectual functioning has been reported in the medical literature for Duchenne muscular dystrophy patients than for normals or other control groups. The reason for this finding is thought to be some type of abnormal central nervous system functioning. Recently, there has been strong evidence to suggest that verbal ability, as reflected by the Wechsler Intelligence Scale for Children (WISC) Verbal IQ, may be more commonly and significantly impaired than is nonverbal ability, as reflected by the WISC Performance IQ.

The purpose of the present article is twofold: first, to introduce a recent, comprehensive review of intellectual functioning in Duchenne muscular dystrophy into the psychological literature, and second, to highlight some of the methodological issues involved in the assessment of intelligence in this population. It is important to provide a basis for future attempts to relate intellectual deficit in Duchenne muscular dystrophy to neuropsychological and neurobiological parameters of the disease. I hope this approach will also prove useful in the study of brain–behavior relationships in other physical diseases that

Note. WISC refers to the Wechsler Intelligence Scale for Children; WAIS refers to the Wechsler Adult Intelligence Scale; S-B refers to the Stanford-Binet Intelligence Scale; IIS refers to the Infant Intelligence Scale. Perf. stands for the Performance scale of the WISC, and V–P stands for Verbal–Performance discrepancy on the WISC.

have behavioral correlates. Reviewed in detail are studies since 1960 of intellectual functioning in Duchenne muscular dystrophy.

Studies Prior to 1960

A higher prevalence of mental retardation than is found in the general population was documented by numerous reports prior to 1960 (Becker, 1953; Del Carlo Giannini & Marcheschi, 1959; Duchenne, 1868; Erb, 1891; Gowers, 1879; Zellweger, 1946) that studied only patients with Duchenne muscular dystrophy. Several earlier studies, however, did not report a higher incidence of mental retardation. They either reported on a mixed group of dystrophies (Bell, 1943; Morrow & Cohen, 1954; Schoelly & Fraser, 1955) or found the degree of intellectual impairment to be relatively mild (Walton & Nattrass, 1954). These earlier studies frequently involved clinical rather than psychometric evaluation of the retardation.

Studies Since 1960

Decline in General Intelligence

Table 1 contains a summary of studies since 1960 of intellectual functioning in Duchenne muscular dystrophy. There is only one, which reported on a group of Duchenne patients using formal psychometric assessment, that did not suggest a higher than normal incidence of mental retardation or a significantly lower than average overall IQ. Sherwin and McCully (1961) studied 15 children with Duchenne muscular dystrophy who ranged in age from 10 to 14 years. All were confined to a wheelchair. The verbal portion of the WISC was administered to all children. Mean Verbal IQ was 103 and ranged from 90 to 120.

All other studies have reported a lower than normal general or Full Scale mean IQ and/or a higher than normal incidence of mental retardation (Allen & Rodgin, 1960; Black, 1973; Cohen, Molnar, & Taft, 1968; Dubowitz, 1965; Florek & Karolak, 1977; Gamstrop & Smith, 1964; Karagan & Zellweger, 1978; Kozicka, Prot, & Wasilewski, 1971; Marsh & Munsat, 1974; Michal, 1972; Nakao, Kito, Muro, Tomonaga, & Mozai, 1968; Prosser, Murphy, & Thompson, 1969; Rosman, 1970; Worden & Vignos, 1962; Zellweger & Hanson, 1967; Zellweger & Niedermeyer, 1965). The mean IQs ranged from 68 to 91, with most about 1 *SD* below the general population average. Cohen et al. (1968), Florek and Karolak (1977) and Prosser et al. (1969) studied in detail the distribution of IQs in their samples. They concluded that the entire IQ distribution of the dystrophic children was shifted downward by 1 *SD* compared with the normal IQ distribution. Consequently, they reasoned that even those patients with an average or above-average IQ were reduced in intellectual ability compared with what would be expected if they did not have the disease.

Control Groups

The study of the intellectual functioning of relatives and affected and unaffected siblings has yielded some consistent and interesting results (Cohen et al., 1968; Kozicka et al., 1971; Prosser et al., 1969; Worden & Vignos, 1962). These studies uniformly reported higher mean IQs for the unaffected siblings and relatives (e.g., parents, aunts, and uncles) than for the affected siblings. Further, there was concordance in level of IQ between Duchenne patients and their affected siblings. The IQs of Duchenne patients also tended to follow the intellectual genetic history of the family, that is, severe retardation was found in patients from dull families, whereas normal intelligence was present in patients from bright families.

Groups of Duchenne patients have also been compared with a variety of control groups in the assessment of their level of intellectual functioning. Groups with chronic or physical incapacities such as diabetes mellitus (Worden & Vignos, 1962), spinal muscular atrophy (Florek & Karolak, 1977; Kozicka et al., 1971; Worden & Vignos, 1962), and postpoliomyelitis (Michal, 1972) all manifested average mean IQs, whereas Duchenne patients manifested below-average mean IQs.

These findings on relatives and other control groups are parsimonious, given the general finding that the distribution of IQ in

the Duchenne patients is shifted downward about 1 *SD* from the normal distribution.

Early Impairment of Verbal Intelligence

The conclusion gleaned thus far, that there is a generally decreased overall or Full Scale IQ in patients with Duchenne muscular dystrophy, is exceedingly impressive. Several investigators (Black, 1973; Prosser et al., 1969; Sherwin & McCully, 1961; Worden & Vignos, 1962; Zellweger & Hanson, 1967; Zellweger & Niedermeyer, 1965) have sought to associate a differential pattern of impairment with a lower Verbal than Performance IQ in patients with muscular dystrophy, but were either unsuccessful or did not explain the finding of a depressed Verbal IQ.

Marsh and Munsat (1974) were the first to document an early impairment of verbal intelligence in Duchenne muscular dystrophy. They studied 34 boys with Duchenne muscular dystrophy who ranged in age from 5 to 15 years. Of the subjects, 16 were mildly physically impaired, and 18 were moderately or severely disabled by the disease and required placement in a wheelchair. All were tested with the WISC. The mildly disabled group had a significantly lower Verbal scale IQ ($M = 85$) than Performance scale IQ ($M = 98$). However, for the moderately or severely disabled groups there was no significant difference between their Verbal scale IQ ($M = 88$) and their Performance scale IQ ($M = 90$). All children in the mild group were still ambulatory and, with one exception, were less than 10 years of age. Marsh and Munsat concluded that verbal intelligence was depressed and nonprogressive in these cases of Duchenne muscular dystrophy. On the other hand, Performance IQ tended to decrease with time as the physical disability interfered with the Performance scale items.

The authors noted that prior to their study there was no available published report of verbal and performance intelligence testing of dystrophic children using only the WISC. All previous studies had used two or more different intelligence tests to cover the age range in their samples. Further, in a detailed review, Marsh and Munsat pointed out that the various tests used were not truly equivalent (Barclay & Carolan, 1966; Hannon & Kicklighter, 1970) and that real differences may have been obscured by the use of several different measures.

Karagan and Zellweger (1978) attempted to replicate the findings of Marsh and Munsat and to study the pattern of Verbal and Performance IQ in this population in more detail. They studied intellectual functioning in a group of 53 boys with Duchenne muscular dystrophy. All the children were under 10 years of age and were ambulatory, that is, they were Stage 5 (Zellweger & Hanson, 1967) or less of their disease. All were administered the Verbal and Performance scales of the WISC; mean Verbal IQ (81) was significantly lower ($t = 4.48$, $p < .001$) than Performance IQ (88). Further, the range of Verbal IQs (58–108) was more constricted and the distribution more skewed than was the range (51–118) and distribution of Performance IQs. The mean Verbal–Performance discrepancy score was -7, significantly lower than the score for the standardization sample of the WISC, which was 0 (Seashore, 1951).

Two Patterns of Intelligence Test Performance

In an effort to analyze this pattern in more detail, Karagan and Zellweger (1978) dichotomized this sample first at the mean (-7) of the Verbal–Performance discrepancy distribution. Two distinct patterns of intelligence test performance emerged. Both groups demonstrated depressed mean Verbal IQs of 81. However, the first group, with a Verbal–Performance discrepancy score that was less than or equal to -7, had a mean Performance IQ of 97. The other group, with a Verbal–Performance discrepancy score that was greater than -7, also had a significantly lower than normal Performance IQ (78).

Relationship of IQ to Psychosocial Factors

Emotional Factors

Studies prior to 1960 (e.g., Morrow & Cohen, 1954) generally attributed any identi-

fied intellectual deficit in Duchenne muscular dystrophy to emotional factors associated with chronic and fatal illness. Although Allen and Rodgin (1960) and Florek and Karolak (1977) identified in the patients in their studies emotional components that could have had a depressing effect on their level of intellectual functioning, these components could not account for the overall depression of IQ, particularly the lower IQs.

Karagan and Zellweger (1978), Kozicka et al. (1971), Marsh and Munsat (1974), and Prosser et al. (1969) did not find the generally lower IQs of dystrophic patients to be the result of secondary or environmental effects of the disease. Kozicka et al. found an average IQ (92) in their control group of patients with spinal muscular atrophy who were about as equally chronically ill and physically disabled as the Duchenne patients, who had a mean IQ of 76. Karagan and Zellweger, Marsh and Munsat, and Prosser et al. concluded that psychosocial factors have little influence on the depressed IQs of Duchenne patients for several reasons. First, the depressed intellectual functioning is present at an early age. Second, most young children with Duchenne muscular dystrophy are no more than minimally restricted in mobility and thus are able to adequately explore their environment. And finally, most of the younger children in these studies either were enrolled in a regular school program or were placed in special programs solely on the basis of their lower mental functioning, and they did not manifest educational handicaps directly attributable to their physical disability.

Socioeconomic Status

No relationship has been demonstrated between socioeconomic status and IQ, except that between extreme classes the IQ differences are not unlike those for the general population (Cohen et al., 1968; Florek & Karolak, 1977; Prosser et al., 1969; Worden & Vignos, 1962; Zellweger & Niedermeyer, 1965). Prosser et al. commented that at both the low and middle socioeconomic levels, the dystrophic patients have lower IQs than do their normal sibs.

Relationship of IQ to Physical Factors

Serum Enzymes

Worden and Vignos (1962) found no relationship between IQ and creatinuria or serum aldolase. Prosser et al. (1969) looked at the relation between creatine phosphokinase (CPK) and IQ in relatives of Duchenne patients. In each family there was no difference in mean IQ between carriers and normals (both male and female). There was also a low nonsignificant correlation between the highest recorded CPK level of each carrier and her IQ. No known study has reported on the relationship between CPK level and IQ in the Duchenne patients themselves.

Sporadic Versus Familial Cases

Although Dubowitz (1965) found that a positive family history for the disease was much less frequent in patients of normal intelligence than in retarded patients, these findings were not supported by Prosser et al. or Zellweger and Niedermeyer (1965).

Severity of Disability

In several studies, IQ was unrelated to severity of disability (Allen & Rodgin, 1960; Black, 1973; Cohen et al., 1968; Kozicka et al., 1971; Nakao et al., 1968; Prosser et al., 1969; Worden & Vignos, 1962; Zellweger & Hanson, 1967), despite two reports suggesting a deterioration in intellectual functioning with disease progression (Dubowitz, 1965; Florek & Karolak, 1977). However, as noted previously, Marsh and Munsat (1974) reported a lower WISC Performance IQ in their patients who were physically more significantly impaired and concluded that the lower Performance IQ was a function of the interference of the physical disability with Performance scale items. This, of course, would also tend to produce a lower Full Scale IQ.

The findings of two reports suggest an interesting phenomenon with respect to Verbal IQ over time. Prosser et al. (1969) found a significant correlation of .38 between age and Verbal IQ in 39 of their patients. Karagan and Zellweger (1976; Karagan & Zellweger,

Note 1) reported on a preliminary test–retest study of the intellectual functioning of 22 children with Duchenne muscular dystrophy. The children were tested with the WISC first when they were under age 10 and at less than Stage 6 of their disease (ambulatory) and again when they were not ambulatory, an average of 48 months later. Again, consistent with their findings on 53 young dystrophic patients (Karagan & Zellweger, 1978), two groups emerged. On initial testing, the mean Verbal–Performance discrepancy score for the 22 patients was −11. The group of 11 patients with a Verbal–Performance discrepancy score that was less than or equal to −11 had an initial Verbal IQ of 79, but on retesting they had a mean Verbal IQ of 87 ($p < .10$). The mean Performance IQ of 99 on initial testing dropped to 88 ($p < .05$). The other group of 11 patients, which had on initial testing a Verbal–Performance discrepancy score that was greater than −11, had identical scores on test and retest—mean Verbal IQs of 79 and mean Performance IQs of 78. Neither group was significantly different in terms of age or stage of the disease at the time of the first or the second testing.

Abnormal Brain Functioning

Although most authors have concluded that the intellectual deficit is related to abnormal brain functioning (Allen & Rodgin, 1960; Cohen et al., 1968; Dubowitz, 1965; Karagan & Zellweger, 1978; Marsh & Munsat, 1974; Michal, 1972; Prosser et al., 1969; Rosman, 1970; Schorer, 1964; Worden & Vignos, 1962; Zellweger & Hanson, 1967), several studies have reported a high percentage of abnormal electroencephalogram (EEG) findings in patients with Duchenne muscular dystrophy (Florek & Karolak, 1977; Kozicka et al., 1971; Nakao et al., 1968; Zellweger & Niedermeyer, 1965). Further, these studies also reported a high correlation between the severity of the intellectual deficit and the severity of the EEG findings. This finding provides some support for the notion that the intellectual deficit is based on some physical parameter of the disease that affects central nervous system functioning as opposed to the notion that the intellectual deficit is solely secondary to psychosocial factors.

Progression of the Disease

Three studies provide some interesting but tentative and speculative data regarding the relation between IQ and progression of the disease. Rosman (1970) reported on 10 patients with Duchenne muscular dystrophy and found that both the clinical myopathy and the severity of histopathological changes paralleled intellectual functioning: The patients with the most severe involvement of muscle were those patients with the most severe degree of intellectual impairment. This relationship was independent of age of onset or of the duration or severity of the myopathy.

Nakao et al. (1968) found in 77 Duchenne patients that the rate of inferior intelligence was high (45%) when the disease was of 6 to 11 years duration and was low (20%) when the disease was of more than 11 years duration. They concluded that cases of inferior intelligence pursue an unfavorable course.

Karagan and Zellweger (1976; Karagan & Zellweger, Note 1) in their preliminary test–retest study of 22 Duchenne patients, found that the 11 patients with a Verbal–Performance discrepancy score of less than or equal to −11 progressed from stages 2 and 3 of the disease to Stages 8 and 9 in an average of 66 months. On the other hand, the 11 patients with a Verbal–Performance discrepancy of greater than −11 (i.e., both Verbal IQ and Performance IQ were depressed) progressed more rapidly, in an average of 38 months ($p < .10$).

Conclusion

Patients with Duchenne muscular dystrophy, traditionally thought to be a primary disease of muscle, manifest a higher incidence of mental retardation and decreased intellectual functioning than the general population. There is strong evidence that this decrease is the result of abnormal central nervous system functioning. Although it has recently been suggested that the disease may be secondary to a neuronal defect or to a generalized disorder of protein synthesis and membrane, no

proof of any of the proposed etiologies exists. The specific mechanisms underlying the disease itself and the accompanying intellectual deficits are unknown at the present time. However, a relationship between the intellectual deficit and the disease is an intriguing possibility.

The entire IQ distribution of patients with Duchenne muscular dystrophy appears to be shifted downward by about 1 *SD* compared with the normal IQ distribution. The IQs of these patients follow the genetic intellectual characteristics of the family, and there is high concordance between the intellectual levels of affected siblings. Duchenne patients typically have significantly lower IQs when compared with a variety of control groups who have chronic disease or physical incapacity. Verbal ability, as defined by the WISC Verbal IQ, is depressed at an early age and appears universally affected in Duchenne patients. Some patients, however, manifest a significant deficit in both Verbal and Performance IQ on the WISC.

There is no evidence to date that relates IQ deficit to serum enzymes, sporadic or familial etiology, age of onset of clinical symptoms, or the severity of disability. However, Performance scale IQ does decline over time as a function of the interference of physical disability with performance scale items. There is no evidence of any intellectual or cerebral deterioration. In fact, there is some suggestion that in some patients Verbal IQ manifests a modest increase over time.

Finally, there are several reports that suggest that the more severely affected a child's intellectual functioning is, the more rapidly the disease progresses. The evidence for this is by no means unequivocal yet.

What appears necessary at this juncture is to identify other neuropsychological characteristics of this disorder and, in turn, to relate these as well as the intellectual deficits to physical parameters of the disease. These factors, of course, do not appear to relate in a simple fashion. The study of neuropsychological aspects of other myopathic disorders is likewise important, particularly because these intriguing yet unfortunate human maladies have received relatively little attention in the psychological literature.

Research on the Effects of Disconfirmed Client Role Expectations in Psychotherapy: A Critical Review

Paul Duckro
Malcolm Bliss Mental Health Center, St. Louis, Missouri

Don Beal and Clay George
Texas Tech University

This article critically examines the pervasive assumption found in psychotherapy literature that disconfirmation of client role expectations has been demonstrated to be a negative influence in psychotherapy. When the empirical literature is examined, this hypothesis does not appear to be as conclusive as has been suggested. In fact, the empirical studies are evenly divided in supporting this hypothesis. Implications for future research are discussed.

The expectations of client and therapist have for some time been postulated to be important influences in psychotherapy. In a monograph-length review and analysis of the early expectation research, A. Goldstein (1962b) extracted two types of expectations relevant to the study of psychotherapy. These two types were characterized as (a) prognostic expectations and (b) participant role expectations. The former were defined as the assessments of therapist and client regarding the probability of success in the therapeutic intervention. The latter were defined as the anticipations held by therapist and client regarding the behavior that will be displayed in the psychotherapeutic relationship by both participants. Researchers have hypothesized, for example, that clients bring to psychotherapy certain preconceived ideas about what the psychotherapist will do and how the client should behave.

The present review focuses on this second category—participant role expectations. More specifically, the review examines extant research that bears on the hypothesis that failure to confirm client expectations of the therapist's role results in negative consequences. In many ways, this hypothesis has already come to be accepted as fact by a large proportion of the psychological community. In the common wisdom, it enjoys the status of a virtually unquestioned assumption. Many such allusions to the "demonstrated" relationship of disconfirmed client role expectations and various dependent variables come across the desk of even the casual reader of research in psychotherapy. To demonstrate this point, three such allusions are presented here. That all three examples are drawn from recent, scholarly reviews of related areas of research only serves to emphasize the pervasiveness of the assumption that disconfirmation of client role expectations has been demonstrated to be a negative influence in psychotherapy.

First, Lorion (1974a) reported that "the importance of patient expectations to treatment variables . . . has been demonstrated" (p. 347). He felt sure enough of this statement to cite in support only seven representative studies that used five different types of dependent variables. Second, Baekeland and Lundwall (1975), in an extensive review of the psychotherapy dropout literature, wrote that "it is known that discrepant expectations about treatment promote drop-

ping out" (p. 758). This inference was supported by the citation of six studies, five of which were published prior to 1966. Thus, these authors showed little hesitation about accepting the validity of the disconfirmed expectations – negative consequences hypothesis. Third, Heitler (1976) made reference to the "substantial body of theory and research evidence" (p. 340) that indicates that some mutuality of patient–therapist role expectations is crucial. He was so confident of this generalization that he cited only six references in support.

Each of the preceding examples demonstrates the extent to which the hypothesized relationship of disconfirmed expectations and negative consequences in psychotherapy has been incorporated into the belief system of the field. The articles cited were not selected because they are unique. On the contrary, they represent a pervasive assumption among clinical researchers. The examples are particularly forceful because they appear in the context of high quality scholarly papers.

The present review was undertaken to examine more systematically whether the assumption of *proven* for the role expectation hypothesis is warranted by the available empirical evidence. The literature is discussed in the following order. First, descriptive expositions of client role expectations are presented briefly. Second, the theoretical and experimental background leading up to A. Goldstein's (1962b) keystone monograph is summarized. Third, the experimental literature since 1962 that deals with the question of the negative consequences of disconfirmed role expectations in psychotherapy is reviewed. Fourth, this literature is discussed in terms of its implications and ambiguities.

Descriptive Studies

A wide range of studies have empirically demonstrated the existence of client expectations about the therapist's role. Apfelbaum's (1958) work is perhaps the classic descriptive study in this area. Using outpatients of a university psychiatric clinic, Apfelbaum cluster analyzed the clients' Q sorts that reflected their pretherapy expectations of the therapist's attitudes and interview behavior. The resulting clusters suggested three major types of client role expectation: (a) the nurturant therapist—giving, protecting, and guiding without pushing or criticizing; (b) the model—well adjusted, diplomatic, a permissive listener but not protective; and (c) the critic—analytical, critical, and demanding considerable responsibility from the client.

Heine and Trosman (1960) identified two types of role expectations held by clients regarding the psychotherapy process. They called these two types of expectations the guidance model and the collaboration model. By far, most of the outpatients in their sample held expectations of psychotherapy that clearly fit the guidance model. They saw the therapist as the source of diagnostic information, of advice, and of medicine. Therapists, on the other hand, anticipated a therapy relationship closer to the collaborative model. They were generally less directive in style and were not oriented toward the use of diagnosis or psychopharmacological agents.

Finally, Begley and Lieberman (1970) broke down client role expectations in still another way. Using a modified version of a questionnaire developed by McNair and Lorr (1964), they identified two clusters of patient expectations of the therapist's role. One patient group anticipated an active, directive, but warm therapist. The other group expected a more passive, detached, objective therapist.

Using these and other approaches to the measurement of client expectations, a number of investigators have limited themselves to reporting the types of expectation predominant in their sample in the hope of determining the characteristic expectations of various populations. Many such reports indicated that the samples anticipated directive therapists. Patients expected the therapist to be warm but still firmly in control of the therapy session. For example, Thomas, Polansky, and Kounin (1955) found that university students characterized the helpful therapist as more directive, that is, willing to offer advice and to structure the situation. Chance (1957) studied a group of mothers who were in therapy concurrently with their children. She found that the

mothers projected their therapists' characteristics in idealized terms. They expected the therapist to function in the interviews as an active, directive, and supportive teacher. Cundick (1963) reported that college student outpatients expected an active and personally involved therapist. However, both clients and therapists agreed that the client had primary responsibility for the direction of the interview. This aspect of their expectation is different from the findings of the previous two studies. Finally, Tinsley and Harris (1976) found that their sample of college students did expect the therapist to be both expert and genuine in personal communication. Interestingly, this group did not generally expect that the therapy would be successful.

Correlates of Client Expectations

Not too far removed from the purely descriptive study of client expectations of therapist role, other researchers have used correlational designs to study the relationship of expectations to various client or psychotherapy variables.

Apfelbaum (1958) found the three role expectation factors in his study to be differentially associated with clients' Minnesota Multiphasic Personality Inventory profiles, rate of dropping out of psychotherapy, hours in therapy, and sex differences. Jacobs, Muller, Anderson, and Skinner (1972) studied the efficiency of several predictors of improvement in hospitalized patients. They found that expectations of a low-directive, less concerned, and less sensitive therapist were the strongest single predictor of negative outcome ($r = .31$).

Caine, Wijesinghe, and Wood (1973) compared persons with expectations of a directive, authoritative therapist to persons who expected the client to be a more collaborative partner in the process of therapy. They found that persons who expected the more directive therapist were significantly more externally directed, tended to be convergent rather than divergent thinkers, and scored higher on the Conservatism scale. Baldwin (1974) reported that university students who expected the therapist to be planned rather than spontaneous in his or her intrasession behavior were more likely to be repressors than sensitizers. In addition, repressors considered therapist personality to be a less important variable in therapeutic outcome than did sensitizers.

Based on his own work and a review of other research, Lorion (1974a, 1974b) concluded that expectations for psychotherapy are not related to socioeconomic status (SES). He reported that subjects from all SES levels tended to verbalize similar expectations of therapist behavior. Low SES clients did not express significantly stronger anticipations of an active, problem-solving therapist style. Supporting this position is Bent, Putnam, Kiesler, and Nowicki's (1975) report that their sample of relatively well-educated community mental health center outpatients expected to receive advice and medicine to solve their problems. These anticipations were not particularly different from those reported for a group of low SES outpatients by Overall and Aronson (1963). Garfield and Wolpin (1963) studied a group of young, predominantly low SES clients in which 67% expected types of therapist behavior that put considerable responsibility on the client to help himself or herself. However, Garfield and Wolpin also asked these clients what type of therapist behavior they preferred. In contrast to their expectation, the clients generally preferred to be given advice. This finding raised the question of the interaction between expectation and preference. The distinction between these two very different concepts has very seldom been made by researchers in the area. As we point out later in the article, the failure to make this distinction has been a source of ambiguity in the literature.

Perhaps the most justified conclusion from this series of descriptive and correlational studies is that expectations of therapist behavior will vary considerably among different samples and even within any given sample. In addition, the Overall and Aronson (1963) study hints that disconfirmed expectations might lead to negative results. Bent et al. (1975), in their descriptive re-

port, stated that this question—about the role of expectation in the outcome of treatment is the next logical question to be addressed by their research. They are correct, of course, in assigning a high priority to the question. The existence of client expectations per se is of little importance if the failure to acknowledge or confirm these expectations does not affect the therapy outcome or process. However, it must be recognized that a substantial body of research has been addressed to this question. In fact, as suggested earlier, the hypothesized relationship between disconfirmed expectations for therapist behavior and negative consequences in therapy has apparently been awarded factual status in much of professional psychology. The examination of the extant research that bears on this hypothesis is the crux of the present effort to ascertain whether its status as *demonstrated* is justified.

Theoretical and Experimental Background: Research Before 1962

Interest in the impact of client role expectations in psychotherapy was already evident by the early 1950s. Initial efforts provided at least explicit speculation on the importance of role expectations in psychotherapeutic treatment (e.g., Kamm & Wrenn, 1950; Seeman, 1949).

Kelly (1955) considerably elaborated the theoretical underpinnings of the early propositions regarding client role expectations in psychotherapy. He postulated that almost any client already holds a highly personalized conceptualization of the nature of the psychotherapy relationship and of the psychotherapist's role within that relationship even prior to the initiation of treatment. Kelly argued, on the basis of his theoretical position, that the psychotherapist must accept the client's preconception of the therapist's role, at least in the beginning stage of therapy. Failure to confirm the client's expectations results in confusion or disappointment on the part of the client. In Kelly's formulation, therefore, the therapist cannot ignore or reject without negative effect the client's anticipations, even though the therapist may attempt in the long run to change the role he or she initially accepts.

Danskin (1955) also posited that the effective therapist typically attempts to play the role expected of him or her by the client. On the other hand, Patterson (1958) argued that there are more and less effective ways to conduct therapy. He favored the low-directive, client-centered approach. Patterson's position was that therapists should not attempt to meet client expectations for therapist behavior. He admonished them to help clients, if necessary, learn to respond favorably to the low-directive therapy style.

At the same time, early empirical efforts to examine the expectation hypothesis were also under way. McGowan (1955) reported that clients in his sample experienced equivalent levels of satisfaction regardless of the style used by the counselors. Satisfaction was related, however, to the perceived expertise of the therapist. A major factor in the perception of a counselor as expert appeared to be his or her ability to form a close, facilitative relationship with the client. Frank, Gliedman, Imber, Nash, and Stone (1957) found that individuals assigned to the relatively unfamiliar (at that time) group method of therapy dropped out of treatment at a much higher rate than did those assigned to the more frequently anticipated individual therapy. The authors speculated that the group therapy experience was too sharply incongruent with the clients' expectations of psychotherapy to permit beneficial participation.

Biddle (1958) built his reasoning on the foundation of earlier work in social psychology. This literature suggested that if one person conforms to the role expectations held by a second person, the first will enjoy greater influence over the second than will a person who does not conform to those role expectations. Biddle hypothesized that analogue subjects would express low satisfaction with a taped therapist who failed to meet their expectations. The results supported the hypothesis only under one of two special conditions. First, when the therapist had some power to punish the client, nonconformity to client expectations led to less

satisfaction. Second, when the client was led to believe that the therapist expected to behave in much the same way as the client expected him or her to behave, then nonconformity by the therapist resulted in the expression of less satisfaction by the client.

Heine and Trosman (1960) used a sample that held predominant expectations of an active, directive doctor and a passively cooperative patient. Their therapists' expectations were generally much more along the lines of the collaborative model. The authors found that patients with the strongest expectations of a directive therapist were much more likely to drop out of therapy than were persons with somewhat less directive expectations. Although therapist styles were not closely controlled in this study, the results were suggestive. Similar findings were reported at about the same time by Skinner and Anderson (1959) and by Hankoff, Englehardt, and Freeman (1960).

Emboldened by these promising data, researchers began major studies, and theoretical propositions were offered. Chance (1959) reviewed the literature up to that point and reported the findings of her own extensive study. She concluded that "this mutuality of expectation may be one of the prerequisites to therapy" (p. 105). Wallach and Strupp (1960) hypothesized, on the basis of the available evidence, that if the client's expectations regarding the therapist were confirmed, then the therapy situation would appear more rewarding and the therapist would be perceived more positively. Therefore, they suggested that congruence between the type of assistance expected and the type of assistance proffered might be an important variable in psychotherapy.

Further, Lennard and Bernstein (1960) reported on their major investigation of the nature and interrelationship of role expectations and therapist–client communication in the psychotherapy interview. Their results suggested a significant relationship between the degree of dissimilarity of the participants' role expectations and the degree of dysfunction in the communication system. They concluded that when the expectations were very dissimilar, the resultant strain in the dyadic interpersonal system placed that system in proximate danger of disintegration. Finally, A. Goldstein (1962a, 1962b) comprehensively reviewed the literature that directly and indirectly bore on the influence of role expectations in psychotherapy. On the basis of those data, he adopted the position that the mutuality of participant role expectations is indeed an important influence in psychotherapy. He argued that the available evidence indicated that adverse effects follow the disconfirmation of client expectations of the therapist's role. Goldstein also urged that the logical next questions be investigated, such as the endurance of the alleged adverse effects and the malleability of clients' incongruent role expectations.

In summary, the early research in this area constituted an auspicious beginning. It may be due in part to the enthusiastic response elicited by this early work that the hypothesized impact of disconfirmed role expectations has become such a common assumption today. Nevertheless, a review of the efforts since 1962 to validate and extend the early findings indicates that the post-1962 research did not lend itself to the same unequivocal and enthusiastic conclusions. The discussion of this later research is organized around the various types of dependent variables that were used. It summarizes empirical efforts to demonstrate the effects of disconfirmed client role expectations as reflected in client satisfaction, premature termination, outcome, process, and changes in client expectations.

Experimental Research Since 1962

Client Satisfaction

Isard and Sherwood (1964) reported that client satisfaction was not related to the particular interview style of the counselor as long as that style was similar to the client's expectation of how the interview would proceed. Mendelsohn (1964) found that when clients recognized that the therapist was responding differently from their expectations, they rated the interviewer more critically than did clients whose expectations were con-

firmed. Interestingly, some of the clients failed to recognize that the therapist was responding in a style different from the one they expected. Goin, Yamamoto, and Silverman (1965) examined the satisfaction of those clients in their sample who expected advice from their therapists. Of this group, 72% of those who received advice from the therapist reported satisfaction. Only 57% of those who did not receive advice indicated satisfaction with therapy. Severinson (1966) reported that disconfirmed client expectations of the degree of therapist empathy resulted in lesser client satisfaction. The relationship held without regard to the direction of the disconfirmation. Kumler (1969) found a similar relationship between disconfirmed expectations of therapist age and warmth and lesser client satisfaction. It is important to note, however, that the negative effects resulted primarily from cases in which expectations of high therapist warmth were not confirmed. Therapist warmth was positively related to client satisfaction regardless of client expectation.

On the negative side, Cundick (1963) found no significant relationship between the congruence of client–therapist role expectations and satisfaction with psychotherapy as rated by counselor and client. Geller (1965) reported similar findings. Further, Severinson (1966) and Kumler (1969), who found evidence supporting the negative effect on satisfaction of disconfirmed client expectations of empathy and warmth, respectively, both failed to find similar effects of disconfirmed expectations of therapist directiveness. In addition, Klepac (1970), using only the audio portion of the videotapes presented by Kumler, failed to replicate Kumler's finding that disconfirmed expectations of therapist warmth led to lesser client satisfaction. Consistent with Kumler, Klepac also reported no relationship between client satisfaction and disconfirmed expectations for therapist directiveness. Finally, Gladstein's (1969) research suggested that client expectations for the therapist's role and the psychotherapy process were multidimensional. His data indicated that disconfirmation of role expectations resulted in diminished client satisfaction only when none of the several dimensions of expectation was confirmed. Thus, he argued that any one given expectation is not itself an important factor in psychotherapy.

Premature Termination

Other researchers have used premature termination of psychotherapy as the dependent variable. Overall and Aronson (1963) compared client expectations with drop-out rate from therapy. A *dropout* was defined as a client who failed to return for the second interview. The authors found that clients with especially high expectations of an actively supportive, directive therapist dropped out of therapy at a significantly higher rate. They attributed this result to the fact that their therapists tended to see their own role as less directive and less actively supportive. It is unfortunate that the measure of client expectation in this oft cited study was designed without safeguards against a "yes" set by the respondent. The questionnaire was administered orally by a staff social worker, thus making the danger of yes sets especially strong. This threat to internal validity can be used to formulate an alternative explanation for the authors' observation that, in general, clients tended to expect all things from the therapist. On the other hand, enough variance among clients did exist to establish that nonreturners held expectations that were more directive and, therefore, more discrepant from the prevailing therapist expectations at that clinic than were the expectations of those who did return for their second session.

In a similar vein, Borghi (1968) found himself unable to differentiate terminators from continuers in therapy on measures of ego strength, anxiety, and dependency. Subsequent detailed interviews with these clients strongly suggested that early termination of treatment occurred most frequently when these clients held role expectations that were incongruent with those held by the therapists. One of the most commonly held incongruent expectations was that the therapist would give a great deal of advice. Sandler

(1975) reported that the expectations of therapist behavior held by early terminators were more discrepant from their therapists' own role expectations than were the expectations of those who continued in therapy. Premature terminators tended to expect more advice from the therapist and expected the therapist to be more responsible for leading the interview interaction.

Opposing these positive findings, Goin et al. (1965) found no difference in length of stay between those clients whose expectation of advice was met and those whose expectation was not met. Fiester (1974) reported no relationship between disconfirmed client expectations for therapist role and dropping out of psychotherapy. Similarly, Vail (1974) found no relationship between the extent of the discrepancy between clients' and therapists' role expectations of the first interview and continuation in treatment. Finally, Horenstein (1974) measured the extent to which clients thought their expectations of therapist role were confirmed or disconfirmed in the actual interviews. He found no significant relationship between failure to confirm expectations and dropping out of therapy. There was the suggestion of a nonlinear trend in the data, with disconfirmation contributing more to negative effects than confirmation to positive effects.

Psychotherapy Outcome

Several studies have used psychotherapy outcome as the dependent variable. H. Goldstein (1965) reported that describing the potential therapist to the client in terms congruent with the client's expectations of therapist role was quite instrumental in establishing a placebo effect. The effect was even stronger than that produced by positive prognostic expectancy. Dougherty (1973) matched one group of clients with therapists based on a number of variables including their respective orientations to therapy. He found that these "optimally matched" clients had more success in therapy, as rated by their therapists, than did the poorly matched and nonmatched subjects. Unfortunately, it is not easy to interpret these results, since the therapists' perceptions of success may merely reflect their greater comfort with clients who share their expectations of how psychotherapy will proceed. Gulas (1974) also found that clients whose initial role expectations were highly congruent with those held by their therapists demonstrated greater improvement in psychotherapy than those with less congruent expectations.

On the negative side, Volsky, Magoon, Norman, and Hoyt (1965) found no evidence in their data to support the position that clients' expectations about their role, the therapist's role, or other aspects of the therapy process have an important bearing on psychotherapy outcome. In addition, Horenstein (1974) found no relationship between the disconfirmation of client expectations of therapist role and therapy outcome. As with the premature termination data, he did uncover a nonsignificant parabolic trend, such that disconfirmation of expectation contributed more to unsuccessful therapy outcome than confirmation of expectation contributed to successful outcome.

Psychotherapy Process

Research investigating the effects of disconfirmed expectations on the therapy process has produced results that are equally ambiguous. Clemes and D'Andrea (1965) derived their hypothesis from a consideration of an earlier study (Pope & Siegman, 1962) in which the less structured, low-directive therapist style produced greater anxiety in the clients than did the high-directive style. Clemes and D'Andrea postulated that it was not the low-directive therapist style per se that aroused anxiety during the interviews. Rather, they argued, it was the interaction of that style with the clients' expectations for a high-directive style that was the causal agent. To test their hypothesis, Clemes and D'Andrea measured each client's expectations for high–low therapist directiveness and then manipulated the actual interviewer style to which each client was exposed. They found that, independent of the particular interviewer style, clients whose ex-

pectations were not confirmed reported greater anxiety than their counterparts whose expectations were realized. Unfortunately, this self-rating of anxiety was not confirmed by a complementary card-sort measure of anxiety, leaving the results unclear.

Pope, Siegman, Blass, and Cheek (1972) also found effects of disconfirmed expectations on interview process. These writers experimentally induced in one of their two groups the expectation that the second of two interviews would comprise a test interpretation by the therapist. The control group was correctly informed that in the second session the therapist would ask questions soliciting personal information. This sort of manipulation, of course, is very strong. It is akin to a therapist deliberately misrepresenting his or her therapy style to a new client. It did effect differences in interview speech behavior between the two groups. The experimental group was less orally productive and displayed more avoidance in their speech patterns. Pope et al. interpreted these results as support for the hypothesis that the experimental group would exhibit more strain in the oral interaction of the interview. Ziemelis (1974) also included an expectation manipulation as part of his study of the process of the psychotherapy interview. He reported some effects of the expectation manipulation: In general, a client's expectation that he or she would not get the type of therapist desired resulted in negative effects, as reflected in some of the pencil-and-paper measures of the process. This effect was not reflected in the ratings of the actual depth of interaction.

On the negative side, Warren (1973) reported that disconfirmed role expectations did not result in any lower rating of relationship quality or therapeutic conditions as measured by the Barrett-Lennard Relationship Inventory. In addition, Klepac and Page (1974) challenged the generalizability of the results reported by Pope et al. (1972). The former writers summarized certain relevant aspects of an earlier study in which Klepac (1970) studied the effects of not confirming client expectations for the therapist's level of directiveness. In that investigation, each person was interviewed by a therapist whose level of directiveness was manipulated to be high or low, thus confirming or disconfirming the person's expectation. The interview itself was conducted via closed-circuit television. To maintain the picture on the monitor, subjects were required to press a switch at a given rate. Thus, two measures of process were available. First, the amount of switch pressing was recorded and was understood as an index of the reinforcement value of the interviewer. Second, oral productivity was recorded in a manner equivalent to that used by Pope et al. Klepac's results indicated that persons whose expectations for a low-directive therapist were disconfirmed exhibited significantly more switch pressing than did persons in any other groups. Thus, not only were there no negative effects of the failure to confirm client expectations but there was a distinctly positive effect of the failure to confirm expectations for a low-directive therapist. Finally, Horenstein (1974) also included a measure of interview process: resistance to psychotherapy. As with the drop-out and outcome variables, he found no relationship between confirmation of expectation and degree of client resistance exhibited, but he did note the parabolic trend that was also reported for the premature termination and therapy outcome variables.

Change in Expectation

Another type of dependent variable used in role expectation research has been the extent and direction of change in the expectation itself as a result of its confirmation or disconfirmation. If role expectations are indeed an important influence in psychotherapy, it is hypothesized that they should be rather strongly held. Kumler (1969) reported that client expectations were relatively stable in the face of disconfirmation. However, clients did tend to change their expectations in the direction of very warm therapists, regardless of original expectation. Sandler (1975) noted that there was a reduction of dissimilarity in role expectation as therapy continued but that clients who eventually dropped out of therapy exhibited

a much lesser tendency to change expectations in the direction of actual therapist behavior.

On the other hand, Cundick (1963) found that client and therapist role expectations became significantly more congruent as counseling progressed. Klepac (1970) was unable to replicate Kumler's results using only the audio portion of Kumler's videotape. Klepac reported that expectations changed in the direction of the therapist's actual style. He replicated his own findings in a second study (Klepac, 1970) in which he reported that client expectations regarding therapist directiveness were quite fluid, again conforming to the assigned therapist's style. Finally, Gulas (1974) also found that congruence of client–therapist role expectations increased as therapy progressed.

Shaping Role Expectation

One other approach has been tried in the attempt to demonstrate the hypothesized relationship between disconfirmed role expectations and negative consequences. The logic underlying this research might be reconstructed as follows: If it is important that client role expectations be confirmed, then clients whose role expectations have been systematically shaped toward congruence with actual therapist style should exhibit more positive consequences. Albronda, Dean, and Starkweather (1964) instructed psychiatric social workers to use preliminary client contacts to help clients form accurate expectations regarding the nature of psychotherapy and the roles of the participants. The authors reported that clients who received this treatment dropped out of therapy at a lesser rate and exhibited improved outcome. Hoehn-Saric et al. (1964) reported that role induction interviews significantly improved client outcome in psychotherapy. The role induction interview consisted of a brief session structured to develop accurate expectations of the psychotherapy process. These results were replicated in a later study by Schonfield, Stone, Hoehn-Saric, Imber, and Pande (1969).

Related manipulations have also proven successful. Mosby (1972) used a procedure in which he informed therapists of existing differences between their own role expectations and the role expectations held by their clients. The therapists were told to try to modify their clients' expectations early in therapy to conform more closely with their own. Clients in the experimental condition changed their expectations of the therapist's role more quickly and dropped out of therapy at a lesser rate than did the controls. Heilbrun (1972) attempted to modify client expectations by using a brief pretherapy session in which clients were instructed that counselors of various styles could be equally effective and that the client should try to adapt his or her expectations to the counselor's style to obtain maximum benefit. Heilbrun found that clients characterized by low readiness for therapy demonstrated a lower drop-out rate when they received the pretherapy briefing than when they did not. However, high-readiness clients were not differentially affected by the briefing process.

Contrary to these uniformly positive results, Venema (1972) was unable to demonstrate the relationship between expectations shaped before therapy and positive therapeutic consequences. An important difference between Venema's study and the studies that reported positive findings is that Venema did not use live interaction in the change-of-expectation process. Instead he used a videotaped manipulation of inappropriate role expectations. In using a procedural check, Venema insured that the group exposed to the videotape entered therapy with significantly more accurate expectations of the therapist's role than did the control group. The experimental group also experienced fewer role expectation disconfirmations during the initial interview. Nevertheless, Venema found no relationship between role expectation disconfirmation and attrition. It may be that it was not the modification of expectations at all that effected the positive outcomes in the previous studies. Rather, it may be that the extra personal attention afforded the clients who received the role induction interviews—the one most important condition that discriminates between the

earlier studies and Venema's—accounted for their more positive results. This alternative interpretation is supported by Fernbach's (1975) failure to effect more positive results with clients who received a written clarification of therapist and client roles. In addition, Orenstein (1974) found no statistically significant effects of a role preparation tape and an attraction induction message on subjects' perceptions of the relationship and of the psychotherapist. It might be fruitful to compare in a single study the separate and interactive effects of extra attention and extra information on client expectation and on psychotherapeutic process and outcome.

In summary, a comprehensive review of the available literature suggests considerable ambiguity regarding the validity of the hypothesis that disconfirmed role expectations result in negative consequences. Research since 1962 has not clearly supported the enthusiastic inferences drawn from the early speculative and experimental literature, nor does the hypothesis warrant the assumption of *proven* that it has so often enjoyed in the current literature. The "box score" may be summarized as follows. Single studies are counted more than once if they used two or more distinct classes of dependent variables or two or more clearly distinct independent variables.

Among studies that used satisfaction as the dependent variable, five (45%) supported the hypothesized relationship and six (55%) did not support it. Among studies that used premature termination from psychotherapy as the dependent variable, three (43%) supported the hypothesized relationship and four (57%) did not. Three studies (60%) that used outcome as the dependent variable supported the hypothesized relationship and two (40%) did not. Studies of the effect of disconfirmed expectations on psychotherapy process were evenly split. Three supported the hypothesized relationship and three did not. Among studies that measured the tenacity with which disconfirmed expectations were held, two (33%) found expectations to be held quite strongly. On the other hand, four studies (67%) found expectations to be rather fluid, changing in the direction of the assigned therapist. The former results support the hypothesized relationship; the latter do not. Finally, five studies (62%) found that pretherapy modification of expectations resulted in more positive consequences; three others (38%) found no effects of pretherapy induction efforts.

The empirical foundation for the hypothesized negative effects of disconfirmed role expectations is imbued with a great deal of ambiguity. In only one type of empirical investigation of this problem—the role induction strategy—is there any hint of a predominance of studies in favor of the expectation hypothesis. Even in this research, the interpretations are confounded by the failure of most of the positive studies to separate the effects of extra personal attention from those that resulted from changes in role expectations. Overall, 21 studies (49%) supported the hypothesized relationship; 22 studies (51%) did not. It would be difficult to find a more even split in a research area. The ambiguity is highlighted even more when one remembers the reluctance of so many editors and reviewers to judge favorably those manuscripts that report nonsignificant results and the consequent reluctance of many researchers to submit such results. Clearly, the conclusion that it is important to meet client role expectations in psychotherapy does not deserve the sustained support that it has received. It must be removed from its status as *demonstrated* in the common wisdom of psychology.

Assessment of the Literature

This section considers the contribution of several factors to the state of ambiguity regnant in the role expectation literature. Implicit in the discussion of these factors are implications for improvements in future research design to clarify the importance of client role expectations in psychotherapy.

Klepac and Page (1974) addressed themselves to the problem of contradictory findings between their report and that of Pope et al. (1972). They argued that one factor that contributes to ambiguity in research on role expectations is the tendency of researchers in the area to study imprecisely defined

or globally assessed expectations. Venzor, Gillis, and Beal (1976) found a clear lack of correspondence between subjects' responses to an adjective checklist of preferred therapist characteristics and a quasi-behavioral index of preferred therapist style. They suggested that future studies use measures that are as close as possible to a behavioral representation of the therapist's behavior. Only a few studies have assessed role expectations with video, audio, or written examples of the behavior in question. Further, some investigators have used instruments for the assessment of expectation that use open-ended response formats, which permit considerable subjective bias in scoring. In one case, the items were objectively written, but the questions were asked orally of the patient by an intake worker. Not surprisingly, these investigators reported that the patients expected almost everything from the therapist; that is, they answered *yes* to almost every question that began "Do you expect . . . ?" Methodologically, one must suspect that a positive response bias may have resulted. In other situations, authors have used relatively brief instruments to assess expectations on a number of dimensions. Since only a few items could be applied to each dimension, the question of reliability must be raised. Finally, some researchers have used instruments of adequate characteristics but have elected to measure expectancy for therapist characteristics that are by definition rather broad in nature, for example, therapist personality.[1]

It is this multifaceted tendency toward imprecision that Klepac and Page (1974) held to be a major cause of the inconsistency of experimental findings in the research on client role expectations. They proposed that future research attempt the twofold task of (a) establishing which are the most relevant basic dimensions along which client role expectations may be described and (b) determining the nature of the effects, if any, of failing to meet client expectations along these various dimensions. This paradigm has a real potential for building a more solid empirical basis on which to make judgments regarding the actual relevance of client role expectations to psychotherapy.

A second problem area in the research on role expectations has been the ambiguous definition of the term *expectation*. In the precise sense in which it was originally used by Kelly (1955) in his theory of personality and psychotherapy, and by Apfelbaum (1958) in the classic study of role expectations, expectation was clearly defined as the *anticipation* of some event. There was the implication that the anticipation is held with some degree of certainty. Klepac (1970) and Pope et al. (1972) are examples of later researchers who have been careful to define expectation for their subjects as this same sense of anticipation. However, most researchers have not been so careful in drawing the distinction, for their subjects or for themselves, between this definition of expectation and the alternative, competing connotation that can be attached to the same word. In this alternative connotation, the term expectation can carry the implication that the expector is due, has the right to, or demands that which is expected. This meaning of the term suggests that the person to whom the expectation is extended has some obligation to meet that expectation. To say to another person "I expect you to be forceful with your boss!" clearly may be understood to imply more than mere anticipation. In truth, such a statement uses *expect* to communicate a desire that such behavior will be forthcoming. More precisely, it is a *preference* that some event should occur.

It seems straightforward to state that these two concepts—expectation as anticipation and expectation as preference—are sufficiently different aspects of human cognition to warrant distinct treatment. Nevertheless, most researchers in the area of role expectations have not dealt specifically with this issue (cf. Rosen, 1967). The majority of authors have simply neglected the problem,

[1] The authors are grateful to an anonymous reviewer who noted that expectations of the therapist's personal qualities and expectations of the therapist's behavior may be differentially determined and may respond differently to disconfirmation. This conceptual distinction has not often been made and may warrant closer consideration in future studies.

apparently leaving subjects to interpret expectation as they wished. The interpretation of their results is not clear, therefore, and the variance among studies is not surprising. Some other authors, while indicating that they were studying expectations, precisely defined their independent variable in terms of client preference for some therapist behavior. For example, one investigator's instruction to describe one's ideal therapist is clearly not likely to have elicited client expectations (anticipations) of therapist behavior. Thus, the imprecision with which expectation has been defined is a second factor in the inconsistency of the research results. The series of studies in this area may have intermittently manipulated one of two distinctly different independent variables. The definitional problem is compounded by the fact that few researchers have stayed with this topic for more than one study. This fluctuation has added considerably to the already large variance in what precisely is being assessed as the independent variable.

The third factor discussed in the present article cannot be so definitively stated. It is presented for consideration by researchers in the area. It is speculated that expectation and preference may not only be related, but may be related hierarchically, such that studies of client expectation cannot be unequivocally understood without the simultaneous investigation of preference.

As early as 1955, Shaw noted that client role expectations might be disconfirmed in a desired direction as well as in an undesired direction. Helson (1959, 1964) developed a sophisticated statement of a similar position. He developed this statement as an alternative to the earlier hypothesis regarding the effects of disconfirmed expectation that was presented by McClelland, Atkinson, Clark, and Lowell (1953) in their elaboration of the achievement motive. Helson's hypothesis regarding the effects of disconfirmed expectation was a bipolar one. He postulated that when the expectation under investigation is one that embodies an affective component, then the affective and motivational consequences associated with the disconfirmation of the expectation arise as a function of the *direction,* as well as the intensity, of the discrepancy.

Helson did not question the adequacy of McClelland et al.'s model for explaining and predicting reactions to the disconfirmation of expectations that are primarily sensory in nature. However, he hypothesized that expectations with an affective or aesthetic component are markedly different in nature from expectations of a purely sensory event. He reasoned that the former types of expectations could be ranked along a continuum ranging across levels of desirability, from most preferred to least preferred, passing through a zone of indifference. Therefore, Helson deduced that given some particular affectively toned expectation, a discrepancy from that expectation in one direction along the desirability continuum would elicit reactions very different in quality from those elicited by a discrepancy in the opposite direction. If the event that actually occurs is more desirable than the expected event, the result will be positive affect and approach motivation. Conversely, if the actual event is less desirable than the expected event, the result will be negative affect and avoidance motivation. Further, Helson also predicted that as the actual event extends farther from the expected event along the desirability continuum, it will elicit increasingly strong positive or negative reactions. In summary, it is clear that Helson considered preference to be a more basic variable than expectation, undergirding it so to speak, and one that must necessarily be known if one is to predict the nature of a given person's response to disconfirmation of an expectation.

This bipolar position stands in contrast to the unidimensional theory of reactions to disconfirmed expectations developed by McClelland et al. (1953). The unidimensional position implicitly or explicitly underlies most investigators' hypotheses that disconfirmation of client role expectations in psychotherapy will negatively influence process or outcome. The unidimensional position holds that the resultant affective and motivational states arise solely as a function of the extent of the discrepancy between the actual event and the expected event. A slight dis-

crepancy in either direction will elicit reactions slightly more positive than will no discrepancy. Beyond that point, the larger the discrepancy, the more negative the reaction.

If the unidimensional theory of expectation disconfirmation is adequate, preference should be considered a noninteracting variable with expectation. On the other hand, if the bipolar theory provides a more adequate explanation for affectively and aesthetically toned expectations, then preference must be considered to be a variable inextricably intertwined with expectation and integral to an understanding of reaction to disconfirmation of expectation. The bipolar theory predicts that the preference modifies the quality as well as the quantity of the reaction to disconfirmed expectation.

Block (1964) undertook an empirical comparison of the two theories of reaction to disconfirmed expectation as they apply to client role expectation in psychotherapy. Experienced raters were trained to note all client remarks that expressed a felt discrepancy between the actual therapy experience and the prior expectation. These remarks were categorized in terms of the size and the direction (more preferred – less preferred) of the discrepancy. Manifest client affect and inferred secondary motivational states were also recorded. Approach motives in psychotherapy were operationalized to include such behaviors as taking initiative in talking, presenting new associations and dreams, making productive use of silence, and exhibiting actions and movements that reflect deeper involvement in the psychotherapy. Avoidance motives were operationalized to include such behaviors as evasions, forgetting dreams, angry silences, coming late, threatening termination, and withdrawing to shallower involvement in psychotherapy. The results clearly supported the bipolar position's predictions. Affective responses and inferred secondary motives varied with the direction of the discrepancy. There was no effect of the size of the discrepancy alone. Thus, the question of whether the client's expectations were confirmed or disconfirmed is too simplistic when asked alone. One must also ask whether the person wanted or did not want what he or she expected.

Although Block's study was reported some time ago, and recently was cited in some detail by Meltzoff and Kornreich (1970), researchers in the area of role expectations in psychotherapy have seemingly not grappled with its implications. It appears at least to us that role expectation research has continued to be based on the unidimensional position, although without such specific conceptual elaboration of the basic assumptions on which the hypotheses are based. We hypothesize that inattention to the bipolar position and the resulting failure to account for the preference variable are two of the factors that have led to the currently highly ambiguous state of the research on disconfirmation of expectation in psychotherapy.

Summary

Early research findings lent support to previous speculation regarding the importance of meeting client role expectations in psychotherapy. The beginnings of this research effort were auspicious. Reviewers of the expectation research offered strong statements regarding the importance of role expectation in psychotherapy. Such statements were met with enthusiastic acceptance, in part because they appeared to herald an alliance of social psychology and psychotherapy research. The belief that negative effects result from the failure to confirm client role expectations was quickly and easily accepted into the common wisdom of psychology. This belief is typically considered to be demonstrated by the research and is usually cited as such without encountering serious challenge. A review of the available empirical literature since 1962 revealed that the validity of the disconfirmed expectations – negative effects hypothesis has not been established with certainty. The research was almost evenly divided in terms of support for and lack of support for the hypothesis.

The ambiguous state of the research was discussed in terms of problems in the designs and conceptualizations that have been used. Namely, it was noted that (a) the opera-

tionalization of the independent variable has often not been adequately precise or reliable, (b) the definition of expectation has usually not been clearly specified for the reader or subject, and (c) the theoretical position that has implicitly undergirded almost all the research on role expectation in psychotherapy may not be appropriate for the kinds of affectively toned expectations that are involved in psychotherapy. In conclusion, it would be most appropriate to approach the subject of role expectations more cautiously for the present. Continued research will be necessary to evaluate the true impact of disconfirmed expectations in psychotherapy. This research should incorporate procedures to counter the types of problems that have limited past work. In the interim, it may be unwarranted to continue to publish the many limited reports that describe the various role expectations of different client groups. It may not be important, in a functional sense, what their expectations are. Furthermore, theses based on the so-called established relationship of disconfirmed expectations and negative effects in psychotherapy should be reexamined in light of the fact that their relationship is not as clearly understood as has been supposed.

Taste Aversion and the Generality of the Laws of Learning

A. W. Logue
Harvard University

Results from research on aversions acquired through the pairing of ingested substances with illness have recently been used to challenge the assumption that there are laws of learning that hold across different species and tasks. The taste aversion literature is selectively reviewed and compared with data from traditional experiments in order to evaluate this challenge. Areas sufficiently documented or controversial to warrant inclusion are associative fluidity, conditioned stimulus and unconditioned stimulus characteristics, temporal relationships, obtaining and processing information, and age differences. The conclusion is that in no instance are different principles required to describe taste aversion and traditional learning. In some cases large parametric differences between the two research areas are apparent. It is suggested that at the present time it is not necessary to dispense with the notion of general laws of learning.

An increasingly prevalent position in psychology is that more attention must be paid to previously ignored species-specific and task-specific differences in the general laws of learning and that a reassessment of the field is necessary (see, e.g., Bolles, 1973; Breland & Breland, 1961; Hinde, 1973; Lockard, 1971; Schwartz, 1974; Shettleworth, 1972a; Staddon & Simmelhag, 1971; Weisman, 1977). Two widely cited articles in *Psychological Review* (Rozin & Kalat, 1971; Seligman, 1970) dealt extensively with this subject.

Seligman focused on the number of trials or amount of information needed for learning to occur, a dimension he called preparedness (for similar concepts see Capretta's, 1961, stimulus relevance and Thorndike's, 1932, belongingness). According to Seligman, previous psychological research has assumed that all associations are equally prepared; in fact, the number of trials required for learning to take place can vary a great deal. The degree and direction of variation are a function of the organism's inherited associative apparatus, acquired throughout a long evolutionary history. Seligman believes that contraprepared associations, learning that takes a great many trials to occur, may follow different laws than prepared associations, which take very few trials to occur. The characteristics of learning described by these laws might include "acquisition . . . resistance to extinction; maximum delay of reinforcement, flatness of generalization gradient" (Seligman & Hager, 1972, p. 5).

Rozin and Kalat alternatively maintained that there is no a priori reason to expect degree of preparedness to be predictive of other laws of learning. Their position was that laws of learning for each species and each learning situation evolve in such a way as to maximize survival; two learning tasks equivalent in preparedness may or may not be equivalent in other aspects of learning, such as maximum delay of reinforcement.

Supported by Grant MH-15494 from the National Institute of Mental Health to Harvard University, this article was written while the author was a National Science Foundation Graduate Fellow. It is part of a dissertation submitted to Harvard University in partial fulfillment of the requirements for the PhD degree. Special thanks are due to I. Shrank for his help in all stages of the article's preparation. The continued technical assistance of V. Koster, and comments on previous drafts by P. de Villiers, G. Heyman, R. Mansfield, J. Mazur, P. Rozin, and the editorial staff of *Psychological Bulletin*, are also greatly appreciated.

Requests for reprints should be sent to A. W. Logue, who is now at the Department of Psychology, State University of New York, Stony Brook, New York 11794.

Although Seligman and Rozin and Kalat differ in their beliefs about the manner in which evolution influences the laws of learning, both their views emphasize the importance of this influence. Both stress the necessity of modifying or removing existing general laws of learning to accommodate adaptive specializations in learning.

The area of psychology that has received the most attention, attack, and theoretical speculation with respect to these issues is feeding behavior, specifically, the learning of taste aversions. For many years taste aversion acquisition was known as the bait-shy phenomenon. Barnett (1975) has carefully described how rats, who consume their food in discrete meals, will briefly sample a new food (the bait), wait, and if they get ill, subsequently avoid that food.

Bait shyness was introduced into the laboratory by Garcia and his colleagues (Garcia, Kimeldorf, & Koelling, 1955). They discovered that when a gastrointestinal-like illness, produced in rats by irradiation, was paired with food, the food became aversive (Garcia, Kimeldorf, & Hunt, 1961). Eventually these data came to the attention of the psychological community (Seligman & Hager, 1972), and an onslaught of taste aversion experiments began (Riley & Clarke, 1977). Several procedural refinements were made, including the substitution in many studies of injections of the poison lithium chloride (LiCl) for irradiation, since LiCl is easier to administer (Nachman & Ashe, 1973). The convention in the taste aversion literature has been to use classical conditioning terminology, with the taste as the conditioned stimulus (CS) and the illness as the unconditioned stimulus (US) (Garcia, McGowan, & Green, 1972). This convention is followed here.

The taste aversion experiments appeared to demonstrate that there were many differences between taste aversion and traditional laws of learning. In particular, acquisition of taste aversions despite extremely long delays between the CS and the US (Garcia, Ervin, & Koelling, 1966) and a proclivity for animals to associate tastes and not other stimuli with illness (Garcia & Koelling, 1966) were noted. The implications of these findings were widely discussed, with some authors taking the view that the data could be incorporated into existing, or somewhat modified, general laws of learning (Krane & Wagner, 1975; Mackintosh, 1974; Revusky, 1977d; Revusky & Garcia, 1970; Testa & Ternes, 1977) and others feeling that more extensive revision of the laws was necessary (Kalat, 1977; Shettleworth, 1972a; Zahorik & Houpt, 1977; see Rozin, 1977, for a more detailed analysis of the reactions to the anomalous taste aversion findings).

Two problems were inherent in these discussions. First, the traditional laws of learning used for comparison were not clearly specified. Seligman and Garcia (Garcia, Hankins, & Rusiniak, 1974; Seligman, 1970; Seligman & Hager, 1972) referred to the equipotentiality and contiguity assumptions of Thorndike's (1911/1965) law of effect as principles that have been considered to hold in most situations and in most higher species. The former assumption is directly opposed to the concept of preparedness; it states that all stimuli and responses are equally associable. The latter declares that learning will only occur if the stimuli and the responses involved are in close temporal contiguity. Nevertheless, exactly what qualifies as equivalence of associability is never stated; close temporal contiguity is equally difficult to define. Seligman hinted at additional laws, those regarding generalization, extinction, partial reinforcement, and so forth, but these are also never defined. This is not a problem unique to taste aversion theorists, but a statement of the general condition of learning theory. No list of equations presently exists that accurately describes all that we know about the learning process.

Even if we had a list of the laws of learning, another problem would remain. What constitutes an exception to a general law of learning? As Kalat (1977) has pointed out, to learn more easily does not necessarily mean to learn differently. Bitterman (1975) and Hull (1945) have made a distinction between qualitative and quantitative differences in learning with respect to laws that vary between species. These categories can also be employed to assist in the study of laws that may vary within a species as a function of the stimuli and responses involved, as may be the

case with prepared versus unprepared associations. The quantitative–qualitative question boils down to "whether the performance of all animals can be deduced from a common set of principles or whether different principles are necessary" (Bitterman, 1975, p. 707). Thus, if one were attempting to identify merely quantitative differences between taste aversion learning and the general laws of learning, one would look for cases in which the same equations could be used, only with different parameter values. What seems to be an intuitively more fundamental, qualitative difference would necessitate the use of different equations to describe the acquisition of taste aversions and more traditional tasks (Herrnstein, 1977; see Hull, 1945, for a detailed, though hypothetical, example of this method of analysis).

A moment's consideration of the qualitative–quantitative distinction reveals it to be somewhat arbitrary when carried to extremes. A large change in the value of a parameter is dubbed a quantitative change, while the removal of a term whose value is already near zero constitutes a qualitative change. In other words, the continuum of small to large differences in laws of learning does not easily split into two pieces, quantitative and qualitative. However, this dichotomy is useful for investigating and categorizing differences between taste aversion and traditional learning.

This article reviews and compares results from taste aversion and more traditional learning experiments in an attempt to assess the generality of accepted laws of learning. Clearly this presents some difficulties. At times it is possible to determine for a given situation the consensus with respect to how learning should take place (a general law of learning). In these cases the qualitative–quantitative distinction may prove helpful. At other times, the effort to differentiate between principles that describe taste aversion and traditional learning seems no more than shadowboxing because neither side is able to clearly define its stance. In any case, as a result of the multitude of claims and counterclaims that have been made about taste aversion learning and consequently about the generality of learning principles, a close examination of some of the data should be instructive.

Because of the extensiveness of the taste aversion literature, only well-documented areas are discussed and representative studies cited. Emphasis is placed on controversial and unusual findings. Readers interested in obtaining additional information from the taste aversion literature should see the almost 700 references compiled by Riley and his colleagues (Riley & Baril, 1976; Riley & Clarke, 1977). The areas discussed here are associative fluidity, CS and US characteristics, temporal relationships, obtaining and processing information, and age differences.

A comparison of the physiological bases of taste aversion and traditional tasks has not been included for three reasons. First, there has been a recent review of the physiological taste aversion literature (Bureš & Burešová, 1977). That review in large part covers the issues of concern here. Second, the physiological mechanisms of taste aversions are at this point far from clear. The studies performed most often train the taste aversions and perform the physiological manipulations in vastly different ways, and obtain vastly different results. For example, in studying hippocampal involvement in the acquisition of taste aversions, some researchers have lesioned the ventral or dorsal hippocampus, exposed the subjects once to a taste before pairing it with illness, and then assessed aversion using a one-bottle test (McGowan, Hankins, & Garcia, 1972), whereas others have aspirated most of the hippocampus, exposed the subjects seven times to a taste before pairing it with illness, and assessed aversion using a two-bottle test (Miller, Elkins, & Peacock, 1971). It is not surprising that the results of these studies were inconsistent, with Miller et al. but not McGowan et al. finding taste aversion disruption; reconciliation of their results is extremely difficult. Third, a difference in physiology between two learning tasks does not necessarily imply a difference in overt behavior. Even leaving aside discrepancies due to different sensory systems, activity in two separate areas of the brain can, perhaps through some later common neural path, result in the same external responses. It is those external responses that

we observe and monitor and by which the organism interacts with the rest of the world.

Associative Fluidity

Acquisition

Taste aversions are noted for forming in one trial. This unusual characteristic alone obliges their classification as prepared associations (Seligman, 1970). Testa and Ternes (1977) have suggested that one-trial taste aversion learning results from rats' lifetime experience with tastes and associated illnesses. Experiments with young organisms in which only one trial was needed for an aversion to form strongly suggest that Testa and Terne's explanation is not correct (Galef & Sherry, 1973; Grote & Brown, 1971; Rudy & Cheatle, 1977). There does indeed seem to be an inherited mechanism that enables taste–illness associations to be acquired rapidly.

Nevertheless, this prewiring for rapid learning may not be unique to the acquisition of taste aversions. One-trial learning can also occur, for example, in standard conditioning avoidance paradigms. Avoidance conditioning may occur rapidly, though only when the avoidance response, such as freezing, is the natural defense reaction of a species (Bolles, 1970). In that case the avoidance learning would also be classified as a prepared association.

Although the rapidity with which taste aversions are learned may not signify more than a parametric difference between taste aversion and other learning, it does make the process of acquisition more difficult to observe because of ceiling and floor effects (Kalat, 1977; Revusky & Garcia, 1970). Garcia et al. (1966) circumvented this constraint by use of a procedure that conditioned a weak aversion. They were thus able to observe the development of an aversion over several trials. The amount of saccharin consumed decreased as the number of saccharin–illness pairings increased in a way consistent with learning curves in more standard paradigms (Kimble, 1961; Mackintosh, 1974).

Retention

Once acquired, taste aversions are retained over an extremely long period of time. Experiments have shown retention for as long as 90 days (Dragoin, Hughes, Devine, & Bentley, 1973). Even day-old guinea pigs trained to avoid sucrose after one trial retained their aversions more than a month later (Kalat, 1975). But such long periods of retention are not unusual for aversively motivated learning in general. For example, Hoffman, Fleshler, and Jensen (1963) showed retention of conditioned suppression in pigeons to be virtually perfect 2.5 years after training. Gleitman (1971) extended these findings using rats, and he suggested that long retention may be the rule for classical aversive conditioning.

Extinction

To extinguish a conditioned response an experimenter presents the CS without the US. With repeated exposure to the unaccompanied CS, the conditioned response decreases in intensity or probability until it finally disappears. It has been suggested that taste aversions, since they are prepared, may be much more difficult to extinguish than traditional tasks (Mitchell, Scott, & Mitchell, 1977; Seligman, 1970; Seligman & Hager, 1972). Nevertheless, neither the overall process of extinction nor the rapidity with which it occurs appears discriminably different between taste aversion and traditional learning.

Numerous experiments have shown that extinction of a taste aversion will occur when the CS is repeatedly presented alone (e.g., Baum, Foidart, & Lapointe, 1974; Domjan, 1975; Garcia et al., 1966; Nowlis, 1974). In addition, it has been found that extinction is faster if exposure to the CS is facilitated by making the CS a subject's sole source of some substance of which the subject has been deprived. For example, Grote and Brown (1973) showed that with only one fluid source available water deprivation hastens extinction of a saccharin solution CS by increasing (safe) CS consumption during extinction trials. Similarly, aversion to a sodium chloride solution is extinguished faster when a need for sodium is produced by injections of formalin or by adrenalectomy, or when a need for water is induced by water deprivation or drug injections (Balagura & Smith, 1970). These experiments indicate that the degree of

extinction of taste aversions varies with the amount of CS-alone presentation, as does the degree of extinction in more traditional learning tasks (see also Abelson, Pierrel-Sorrentino, & Blough, 1977).

There is such a large range in the resistance to extinction of tasks acquired in standard conditioning procedures that to make a statement to the effect that taste aversions are more or less difficult to extinguish at best obscures the facts. Characteristics of experimental procedure during acquisition are influential in determining rapidity of extinction (for a review of the literature see Kimble, 1961; Mackintosh, 1974), and this influence also makes it difficult to compare taste aversion with traditional task extinction. A more fruitful approach may be to compare extinction of prepared and unprepared learning, equating as many aspects of the procedures for the two types of learning as possible. Some data relevant to such a comparison already exist (see Seligman & Hager, 1972). However, the ability of the researchers cited in the preceding paragraph to extinguish taste aversions without inordinate difficulties (in Garcia et al.'s, 1966, experiment extinction was complete after three 10-minute sessions) argues against a statement to the effect that taste aversions almost always take longer to extinguish than do responses acquired in traditional tasks.

Summary

Acquisition occurs over time as a CS and a US are presented together. Once CS–US pairings have ceased, responses to the CS gradually decrease, although complete cessation of responding may take years. This process occurs more quickly when the CS is presented without the US, that is, extinction occurs. This description applies equally well to both taste aversion and traditional learning. Further, the data point to no unique temporal aspects of these processes for taste aversion learning; taste aversions are not acquired faster, retained longer, or extinguished over more trials than all other traditional learning tasks. Previous studies of operant and classical conditioning have included a wide range of prepared and contraprepared associations. At most the research indicates that taste aversions are relatively easier to acquire, a quantitative, not a qualitative, difference.

CS and US Characteristics and Their Interaction

Intensity

US. With increasing US intensity, learned taste aversions are more pronounced (Dragoin, 1971; Nachman & Ashe, 1973; Revusky, 1968). This is consistent with other findings in the operant and classical conditioning literature. Ray and Bivens (1968) trained mice on a passive avoidance task and found that with a greater intensity US, learning was more persistent following amnesic electroconvulsive shock. In Passey's (1948) experiment with humans, conditioned eyelid responses were larger and were acquired more quickly when a stronger air puff was used as the US. Finally, Church (1969) has summarized evidence indicating that the extent to which punishment of an instrumental response suppresses that response is a positive function of the intensity of the punishment.

CS. The taste aversion CS also seems to support better conditioning when it is stronger (Barker, 1976; Dragoin, 1971; Nowlis, 1974). Pavlov (1927/1946) observed this phenomenon in his own experiments on salivary conditioning, and Hull (1949) incorporated it into his learning theories as stimulus intensity dynamism. Gray (1965) discussed the more recent evidence for this phenomenon in classical conditioning generally.

Specificity of CS to US

Taste aversion. Garcia and his colleagues, working with rats, were the first to report specificity of CS to US in taste aversion learning. The seminal study (Garcia & Koelling, 1966) found that if both an audiovisual and a taste cue are correlated with illness, only the taste readily becomes aversive. Similarly, if the two cues are paired with shock, only the audiovisual cue readily becomes aversive. Additional work (Garcia & Koelling, 1967; Garcia, McGowan, Ervin, & Koelling, 1968) showed that a taste was easier to

associate with illness than was an odor or the size of a piece of food. Green, Bouzas, and Rachlin (1972), using a more controlled procedure, have also demonstrated specificity of CS to US. They followed rats' saccharin drinking with 1 hour of poisoning, pulsed shock, or continuous shock. Only poisoning suppressed drinking.

The tendency of the taste of the food, rather than any other aspect, to become associated with illness is one of the best known characteristics of illness-induced learning. However, it should be remembered that despite occasional failures (Larsen & Hyde, 1977), it is possible for cues other than tastes to be associated with illness in rats, although often more trials and more careful training procedures are required (Riccio & Haroutunian, 1977; Rozin, 1969). P. J. Best, Best, and Henggeler (1977) summarized a good deal of evidence in support of this statement, but they also pointed out that illness-induced aversions to environmental cues are not as robust as taste aversions. The maximum delay of reinforcement is shorter, and the aversions extinguish faster.

Traditional learning. But what about more standard learning paradigms? Do they also show specificity of CS to US? The answer is yes, although examples are not as easy to find for them as they are for taste aversion learning. Shettleworth (1972b) used three different procedures in her experiments with chicks: punishment with foot shock for drinking water, punishment with shock in the water for drinking, or fear conditioning by pairing exteroceptive stimuli with foot shock while the chicks drank. For the first two procedures, a compound CS consisting of a flashing light plus clicking was associated with shock and controlled behavior. For the conditioned emotional response paradigm, the clicking controlled behavior. However, Shettleworth's studies were not ideal for showing CS to US specificity, as they used different responses and different experimental procedures.

Two operant conditioning experiments did not have this problem. Delius (1968) showed that when pigeons were thirsty and pecking for water reinforcement they were more likely to peck at stimulus cards toward the shortwave (blue) end of the spectrum relative to when they were hungry and pecking for food reinforcement. In Foree and LoLordo's (1973) experiments pigeons pressed a treadle either to obtain food or to avoid shock. Both visual and auditory discriminative stimuli were present. Visual stimuli were prepotent in controlling behavior when food was being obtained; auditory stimuli were prepotent when shock was being avoided.

What these results may indicate is not simply that standard learning can show instances of CS to US specificity, as occur in taste aversion acquisition, but that the frequency of prepared and contraprepared associations is greater and more pervasive than has been previously assumed. Clearly, the preparedness of associations can affect experimental results, and taste aversions are by no means the only example. Only additional experiments will determine the extent of CS to US specificity in traditional learning.

Differences between species. As a result of the influence of Darwin's theory of natural selection, all species are thought to have evolved from some small number of ancestors and thus to have many characteristics in common. This belief in the continuity of the species is fundamental for animal psychologists who spend their careers working with lower organisms, thereby developing principles that many of these researchers hope will one day be applied to human beings. Nevertheless, the taste aversion literature has pointed out some very striking species-specific differences. In particular, for some species gustatory cues do not serve as the most prepared CS in illness-induced learning. Instead, visual cues are prepotent. Wilcoxon, Dragoin, & Kral (1971) provided quail with blue sour water to drink and then poisoned the quail. Aversions were formed to the blue color and not to the sour taste of the fluid. This modality preference is adaptive, for quail's food consists of seeds that are covered by a hard, flavorless shell. To determine what is and is not poison, diurnal birds that consume seeds must use visual cues (Garcia et al., 1974; Gustavson, 1977).

It could be argued that the ability of quail to form visually based illness-induced aversions is solely attributable to the fact that the visual apparatus of quail, diurnal birds,

is so highly developed. But this argument cannot be made for results from taste aversion experiments that employed guinea pigs (Braveman, 1974, 1975b). This species has no difficulties associating visual cues with illness, despite the fact that their visual system is no more developed than that of the rat. In contrast, rats do not easily associate visual cues with illness. Guinea pigs and quail search for their food by day and use their visual systems in this search. Rats obtain food at night using their visual systems to a lesser extent. The stimuli of the modality used in searching for food may be those that are prepared to associate with illness rather than simply the stimuli perceived by the most highly developed sensory system (Braveman, 1974, 1975b).

Gustavson (1977) summarized much of the evidence on the formation of illness-based aversions in different species. He concluded that to a surprising extent, these aversions are formed in a similar manner across many species. The prepotent CS modality differs depending on the particular ecological niche of the species, but overall the effects of CS and US intensity, and the maximum interval between the CS and the US, are strikingly alike across species. It should also be noted that species differences in cue modality predominance are not confined to the taste aversion paradigm (see Kalat, 1977, for a discussion of this point).

CS salience as a function of the US. Not only are some CSs predisposed to be associated with some USs in taste aversion learning but, even more specifically, some CSs may be associated with injections of certain aversive substances and not others. Weisinger, Parker, and Skorupski (1974) have reported experiments showing that if saline is used as the CS it will become aversive if insulin, which decreases blood sugar, is used as the US. However, if formalin, which causes a need for sodium, is used as the US, an aversion to saline will not form. On the other hand, when sucrose is employed as the CS the opposite results are obtained. Domjan and Levy (1977) pointed out the possible evolutionary basis of this behavior: Animals low in blood sugar are unlikely to become ill while consuming sucrose, nor while consuming saline when they are low in salt. In keeping with these findings, Frumkin (1975) was unable to train adrenalectomized (adrenalectomy causes a decrease in body sodium) rats to avoid sodium chloride or to train parathyroidectomized (parathyroidectomy causes a decrease in body calcium) rats to avoid calcium lactate.

Contrary to Weisinger et al.'s and Frumkin's results, Domjan and Levy were able to obtain conditioning of sucrose and saline with both insulin and formalin. Domjan and Levy could not completely isolate the reason for the discrepancy in results, although they eliminated many possibilities. Trent and Kalat (1977) obtained data similar to those of Domjan and Levy. They trained a taste aversion to sodium chloride in sodium-deficient subjects. They attributed their success to the design of the experiment: During testing the rats did not have a strong sodium hunger that would have masked any aversion to sodium. Clearly, even tastes that possess some kind of a positive biological significance can be made aversive in a taste aversion paradigm. This is consistent with the finding that the vaginal, sexual attractant secretion of the female hamster is easily associated with illness in male hamsters (Johnston & Zahorik, 1975; Zahorik & Johnston, 1976).

Generalization of the CS

Variation along more than one stimulus attribute. Generalization of the CS does occur to substances that have tastes similar to the CS. Domjan (1975) reported that after saccharin had been made aversive through contingent poison, casein hydrolysate, but not vinegar, was also subsequently avoided. Domjan drew the plausible conclusion that casein hydrolysate tastes more like saccharin than does vinegar. In experiments in which rats actively ingested LiCl (Balagura & Smith, 1970; Nachman, 1963; D. F. Smith & Balagura, 1969), the taste of the LiCl became an aversive CS and the aversion generalized to NaCl, a substance that causes responses similar to LiCl in the chorda tympani nerve (Nachman, 1963). These results are comparable to those obtained in traditional

conditioning procedures (Sutherland & Mackintosh, 1971).

Variation along one stimulus attribute. By testing for the amount of aversion to stimuli similar to the CS except for variations in one CS attribute, it is possible to determine the shape of a taste aversion generalization gradient. Generalization curves found using the usual laboratory paradigms take one of two basic forms: a straight line with positive or negative slope (stimulus intensity dynamism) or a curve passing through a minimum at the CS. The former is obtained when generalization is investigated along an intensity continuum such as brightness or loudness. The latter is observed with continua that change qualitatively as they are varied, for example, wavelength and pitch.

Despite suggestions that taste aversion generalization curves may demonstrate no stimulus control (Seligman & Hager, 1972), similar curves, and therefore similar equations, describe results of generalization testing in taste aversion and traditional learning paradigms when comparable modalities are employed. Several investigators have performed illness-induced aversion generalization experiments by poisoning after consumption of one saturation of blue water (Czaplicki, Borrebach, & Wilcoxon, 1976), one saccharin concentration (Logue, Note 1), or one salt concentration (Nowlis, 1974) and then testing with varying saturations or concentrations. The results suggested stimulus intensity dynamism with greater aversion as the tested stimulus increased in strength (Czaplicki et al., 1976), a generalization curve that passed through a minimum at its center, showing less aversion to test stimuli either stronger or weaker than the CS (Logue, Note 1), or both (Nowlis, 1974). Since saccharin concentration was the only clearly nonintensity continuum used in these experiments (the taste of saccharin changes qualitatively as its concentration changes; Collier & Novell, 1967), the results are consistent with predictions from the traditional literature.

Hedonic Value of the CS

A much discussed question in psychology is whether a neutral stimulus paired with a reinforcer becomes a signal for that reinforcer or whether the previously neutral stimulus itself acquires some hedonic value (Gleitman, 1974). Taste aversion theorists have claimed that a taste aversion CS is unusual in that it changes in hedonic value when it is paired with the US (Garcia & Hankins, 1977; Garcia et al., 1974; Garcia, McGowan, & Green, 1972; Garcia, Rusiniak, & Brett, 1977). In taste aversion experiments, not only does the organism act as if the CS causes illness but the subject displays other behaviors toward the CS indicating the changed hedonic tone of the stimulus. Garcia, McGowan, and Green (1972) cited as evidence for this that animals avoid the CS from a taste aversion experiment no matter where they encounter it, whereas when a taste is paired with shock the taste is avoided only in the experimental chamber in which the conditioning took place. However, note that money, a traditional, generalized, conditioned reinforcer, is of value even in situations in which it has never been paired with a primary reinforcer.

Additional evidence for the changed hedonic value of a taste aversion CS comes from Garcia et al.'s (1977) report of their observations of predator–prey relationships. These researchers have studied predators' reactions to their natural prey after consumption of the prey has been paired with illness. When presented with a meat carcass previously associated with LiCl, besides showing retching movements, coyotes demonstrate what the authors call *conditioned disgust responses,* including urinating on, burying, or rolling on the meat. A third class of behaviors are *conflict responses,* abnormal responses to the prey that take the place of the usual prey–predator relationship.

These types of responses to the CS are not confined to the taste aversion paradigm. Hearst and Franklin (1977) showed that pigeons will withdraw from a response key that has a negative correlation with grain. Timberlake and Grant (1975) used the presence of a rat as a food predictor for another rat. Subjects in the experiment directed social behaviors, not eating responses, toward the predictive rat. The authors stated that

their experiment provides support for the hypothesis that in classical conditioning a whole set of related responses is conditioned, not just a single reflex. Further, the concept of changed hedonic value has been present for many years in a traditional theory of human motivation under the name of *functional autonomy* (Allport, 1937, chapter 7). According to Allport, some stimuli paired with reinforcement become reinforcing in their own right and reduce drives that are not necessarily the same as those reduced by the original primary reinforcer.

Summary

This section has made abundantly clear the problems that arise in trying to compare taste aversion with so-called traditional learning. Although it was possible to establish some general effects that occur for both taste aversions and traditional tasks, for example, better learning with more intense CSs and USs and generalization of the CS to similar stimuli, other areas were not as easy to evaluate. There is evidence that some target responses in standard learning paradigms are easier to acquire with particular reinforcers than are others. Similarly, there are suggestions in the literature that the CS at least sometimes elicits a complex of interrelated behaviors both for animals acquiring taste aversions and for animals acquiring responses in traditional tasks. Therefore, with respect to specificity of CS to US and the hedonic value of the CS, it is difficult to compare taste aversion learning with the whole of traditional learning. The function that the preceding sections serve is to point out that in these respects the acquisition of taste aversions is not unique.

Temporal Relationship of CS and US

Trace Conditioning

Taste aversions are usually conditioned by first presenting the CS and then after a delay ranging from minutes to hours, presenting the US. This is similar to the classical conditioning procedure of trace conditioning. In a taste aversion paradigm delays of about an hour are common laboratory procedure. Learning has even occurred under optimal conditions with delays of 24 hours (Etscorn & Stephens, 1973). In accordance with what has been reported in traditional learning experiments (Renner, 1964), it has consistently been found that the strength of a learned taste aversion is less with longer intervals between the CS and the US during acquisition (see, e.g., M. R. Best & Barker, 1977; Burešová & Bureš, 1974; Garcia et al., 1966; Kalat & Rozin, 1971; Nachman, 1970; Revusky, 1968; J. C. Smith & Roll, 1967; Wilcoxon, 1977).

Although most experiments in traditional learning have shown that conditioning is possible only with CS–US delays of at most a few seconds (Kimble, 1961), a few experiments have demonstrated learning with longer delays. The latter studies examined the delay of reinforcement gradient by employing long intertrial intervals in two ways: Either reinforcement on one trial determined whether a response would be reinforced on the next trial or reinforcement for a trial was simply delayed until the start of the next trial. The first type of study has been reported by Capaldi (1967), Petrinovich and Bolles (1957), Petrinovich, Bradford, and McGaugh (1965), Pschirrer (1972), and Tyler, Wortz, and Bitterman (1953). In Capaldi's study rats ran in a runway, and reinforcement was presented on alternating trials. Despite 24-hour intertrial intervals the rats learned to run slower on trials that would not receive reinforcement.

Lett (1973, 1974, 1975) performed the second type of long-delay, traditional learning experiments. For her studies she used T mazes and delays of up to 1 hour between when the rat made its choice and was removed from the maze and when it was put back in the maze for another trial and received its reinforcement for the first trial. In a recent investigation (Lett, 1977), reward was given to a subject in its home cage following a session in the T maze. Animals still learned with delays of up to 2 hours between removal from the T maze and reward in the home cage. Lett was able to obtain

long-delay learning only when she removed the animals from the apparatus for the delay.

Lett's experiments have been offered as support for Revusky's (1971, 1977a) concurrent interference theory of long-delay learning. Revusky has stated that the maximum delay possible between the CS and US is an inverse function of the number of additional associations to the CS and US, other than the reference CS–US association, that form during the delay. These additional associations interfere with CS–US learning. Taste aversions are learned over long delays because other stimuli predisposed to associate with illness infrequently intervene between the CS and US. On the other hand, in traditional conditioning procedures employing a light or tone as the CS, other visual and auditory stimuli are very likely to intervene between the CS and US unless the CS–US delay is very short (see Kalat & Rozin, 1971, and Rozin & Ree, 1972, for additional support and criticism of the interference theory of long-delay learning).

Theories other than Revusky's have been offered to explain the differences in maximum delay of reinforcement usually found between taste aversion and traditional learning. An explanation based on the presence of an aftertaste that would bring the CS closer to the US has been sufficiently laid to rest (Garcia, Hankins, Robinson, & Vogt, 1972; Garcia, McGowan, & Green, 1972; Revusky & Garcia, 1970; Rozin, 1969). An alternative explanation relies on evidence of the unusual duration of the gustatory memory trace (Krane & Wagner, 1975). Regardless of which theory one wishes to accept or propose, if there is a difference between taste aversion and standard conditioning with respect to maximum delay of reinforcement it is a quantitative one; the data in question involve simply longer or shorter delays with perhaps some degree of overlap between the two paradigms.

Backward Conditioning

Backward conditioning, learning when the US is presented just prior to the CS, was traditionally assumed to be impossible (Kimble, 1961). But recently some standard learning experiments using more sophisticated procedures have reported backward conditioning (Heth & Rescorla, 1973; Keith-Lucas & Guttman, 1975; Wagner & Terry, 1975). In these experiments, maximum delays between the US and the CS are in the order of seconds. Results from taste aversion experiments are strikingly different. Although the very first attempt to demonstrate backward conditioning was not successful (Garcia & Kimeldorf, 1957), since then backward conditioning has been repeatedly obtained. Still at issue, however, is the maximum delay between the US and CS that will still support learning. Values range from .5 to 12 hours (Barker, Suarez, & Gray, 1974; Boland, 1973; Domjan & Gregg, 1977; Scarborough, Whaley, & Rogers, 1964). Domjan and Gregg reported that the maximum delay depends on the intensity of the CS.

It is not clear why this discrepancy in maximum US–CS delays between taste aversion and more standard learning exists, but it may have something to do with US duration. The US–CS delays in the taste aversion experiments were calculated as the time between irradiation (or poison injection or intubation) and the opportunity to taste. This is an inaccurate estimate, since the US consists of the sensations of illness, not of the manipulation that causes the illness, and since the CS consists of the actual taste, not simply of the availability of a taste. Illness resulting from poison or irradiation may still have been present hours later when the CS was presented, or even hours after CS termination, for an effective combination of backward, simultaneous, and trace conditioning. The traditional experiments all used shock of brief duration. These hypotheses are difficult to test because of methodological problems in measuring illness and aftertastes (see Barker, Smith, & Suarez, 1977, for a more detailed discussion of these issues), but it should be noted that in general, as in traditional learning, the maximum delay with which acquisition will occur in a backward-conditioning taste aversion paradigm is shorter than in a trace-conditioning taste aversion paradigm.

Summary

The temporal relationships between the CS and the US that support learning are not qualitatively different for taste aversion and traditional learning. In both cases, whether the CS or the US occurs first, close temporal contiguity is more effective than very long delays, and trace conditioning is more effective than backward conditioning. Most often, though not always, taste aversion learning is supported by longer delays than are possible in traditional learning. Several attempts have been made to explain this difference by reliance on such factors as the amount of interfering associations during the delay or the duration of the US rather than by reliance on a unique process of taste aversion formation. Nevertheless, it is striking that taste aversions have been acquired in one trial with a 24-hour delay (Etscorn & Stephens, 1973); nothing even approaching this has been demonstrated in traditional paradigms. This distinction between taste aversion and traditional learning appears to be one instance of such a large quantitative difference that simply calling it a quantitative, and not a qualitative, difference seems inappropriate.

Obtaining and Processing Information

Novelty

CS. Taste aversion conditioning appears to be easier with certain tastes than with others. Kalat and Rozin (1970) used the term *salience* to describe this finding. However, as was discussed above, CS intensity affects CS conditionability, and Kalat and Rozin did not equate the subjective intensity of their solutions, clearly a difficult task. In a later experiment, Kalat (1974) found that the degree to which a solution was novel could account for both CS intensity and salience effects. Although in most prior experiments rats had no previous experience with the solutions presented to them, the solutions differed to a varying extent from what the rats were used to drinking, which was plain water. Kalat raised rats on water or a high concentration of a particular solute. He then allowed them to drink a low and a medium concentration of that solute followed by poison. Rats raised on water formed an aversion to the medium concentration, whereas rats raised on a high concentration formed an aversion to the low concentration. There are many additional experiments that have carefully demonstrated the difficulty in associating a taste with illness if the taste has previously been presented without illness (e.g., M. R. Best & Gemberling, 1977; Fenwick, Mikulka, & Klein, 1975; Kalat & Rozin, 1973; Kiefer, Phillips, & Braun, 1977; Revusky & Bedarf, 1967; Siegel, 1974). This is comparable to the procedure in classical conditioning known as latent inhibition. There too a CS presented without a US, and before any presentation of a US, is more difficult to condition with that US (see Lubow, 1973, for a review of the literature).

There has recently been a great deal of controversy in the taste aversion literature over whether noncontingent illness can by itself cause an aversion, or an increased aversion, to novel foods similar to the process of sensitization in classical conditioning (Bitterman, 1976; Garcia, Hankins, & Rusiniak, 1976; Mitchell, 1977; Mitchell et al., 1977; Revusky, 1977b). Appeals to sensitization effects have been used in attempts to explain away the unusual associative properties of tastes with illness. Current evidence indicates that there are two types of enhanced aversion to novel foods following illness (Domjan, 1977). The first is a short-lived aversion to all novel foods, as a direct effect of the poison-induced illness. This phenomenon is observed after taste-contingent or taste-noncontingent poisoning and thus is comparable to sensitization. Second, after taste-contingent poison presentation, a more lasting aversion occurs to novel foods that taste similar to the taste paired with illness. The aversion to the taste paired with illness generalizes to similar novel foods, an associative process (i.e., not sensitization). Therefore if subjects are completely recovered from illness before any aversion testing begins, it is extremely unlikely that any sensitization effects will be observed. Most ex-

perimenters have indeed waited until the animals were no longer ill before beginning testing (for similar opinions and supporting evidence, see Garcia & Hankins, 1977; Revusky, 1977c; Rozin, 1977; Testa & Ternes, 1977; Wilcoxon, 1977; Zahorik, 1977).

US. Parallel to the finding with CSs and contrary to what sensitization would predict, if a US is presented alone and not correlated with a CS, subsequent conditioning of a taste aversion with that US is retarded (Cannon, Berman, Baker, & Atkinson, 1975; Cappell, LeBlanc, & Herling, 1975; Elkins, 1974; Kiefer et al., 1977; Mikulka, Leard, & Klein, 1977). This was demonstrated even when tolerance and addiction effects were controlled for (Bravemen, 1975a; Vogel, Note 2). The complementary US preexposure effect has been noted in traditional conditioning experiments (e.g., Ayres, Benedict, & Witcher, 1975; Mis & Moore, 1973; Siegel & Domjan, 1971).

Learned Irrelevance

Learned irrelevance is the term that Mackintosh (1973, 1974) used to describe an organism's learning that a given CS and US are not correlated. This occurs with random presentations of both the CS and the US and is more deleterious to further conditioning than simply presenting the CS alone (latent inhibition). Mackintosh cited a great deal of evidence to show that organisms can learn a lack of correlation between the CS and the US. So far this phenomenon has not been explicitly investigated in taste aversion learning. This is probably due to the problems inherent in randomly presenting CSs and USs without having some association take place between them as a result of the long delays of reinforcement possible with taste aversions. That taste aversions do not form with extremely long CS–US delays, presumably because the organism learns that the CS is not associated with poison, has been described as demonstrating learned irrelevance in a taste aversion paradigm (Kalat, 1977).

Blocking

There are at least two basic procedures with which to study the blocking effect. Kamin originally reported blocking in 1969 upon showing that prior conditioning with one member of a compound stimulus blocked later conditioning to the other member of the compound when the compound was paired with a US. Revusky (1971) obtained blocking in a taste aversion experiment using this type of a blocking paradigm and taste stimuli. Kalat and Rozin (1972), also employing taste stimuli, were unable to confirm this result; the novel member of the compound stimulus paired with the US still became aversive. However, subsequent experiments have demonstrated that this type of blocking does occur in taste aversion learning (Gillan & Domjan, 1977; Rudy, Iwens, & Best, 1977). Rudy et al. first paired novel exteroceptive cues with illness. Later, acquisition of an aversion to a taste was impeded when the compound of the taste and the familiar exteroceptive stimulation were paired with illness. Gillan and Domjan used only oral stimuli in their experiments.

The second type of procedure used in demonstrating blocking was employed by Wagner, Logan, Haberlandt, and Price (1968). In this method one compound containing two stimuli is paired with the US, and another compound containing one stimulus from the first compound plus a third stimulus is presented but not paired with the US. A test for learning is then conducted with the stimulus common to both compounds. Subjects in Wagner et al.'s experiments demonstrated blocking by responding less to the common stimulus under these reinforcement conditions than when each compound was followed by the US half the time. Luongo (1976) obtained similar results from a taste aversion experiment.

There have been other attempts to manipulate the amount of information provided by a taste CS paired with an illness US (see Kalat & Rozin, 1972; Revusky, Parker, & Coombes, 1977), but since comparable traditional designs have yet to be performed, it is difficult to interpret the taste aversion results.

Conditioned Inhibition

A conditioned inhibitor is a cue that guarantees that reinforcement will not occur when it might otherwise be expected to occur; it has a negative correlation with reinforcement (Kimble, 1961; Mackintosh, 1974). Conditioned inhibition has been demonstrated in taste aversion. M. R. Best (1975) paired saccharin with illness and then saline with no illness. The subjects subsequently chose between saline and some third liquid. Their preference for saline as compared with the other liquid available was greater than that of control animals. In Taukulis and Revusky's (1975) experiment saccharin was always followed by illness, but saccharin accompanied by an odor was never followed by illness. The odor then satisfied three of Rescorla's (1969, 1971) conditions for classification as a conditioned inhibitor: The presentation of the odor with a CS inhibited the conditioned response to the CS, aversion conditioning of the odor was harder than aversion conditioning of a neutral stimulus, and the odor enhanced conditioning to a neutral stimulus when odor and neutral stimulus presented together were followed by reinforcement.

Sensory Preconditioning

The first step in attempting sensory preconditioning is to pair two stimuli. One of them is subsequently reinforced. If the other, nonreinforced stimulus also acquires motivational properties, as if it too had been paired with the reinforcer, sensory preconditioning has taken place. This phenomenon has frequently been demonstrated in traditional laboratory experiments (see, e.g., Brogden, 1939; Rizley & Rescorla, 1972). It has also been shown to occur in a taste aversion paradigm (Lavin, 1976). Lavin exposed rats to two tastes, one right after the other. He then followed a presentation of one of these tastes with illness. The taste that was not paired with illness became aversive. In addition, this example of sensory preconditioning in a taste aversion paradigm occurred only if during the original pairing the two tastes were separated by no more than a few seconds, as in traditional paradigms.

Second-Order Conditioning

Second-order conditioning is similar to sensory preconditioning except that the two stimuli are presented together after one of them has been paired with illness instead of before the pairing (see Rizley & Rescorla, 1972). Although it has been difficult to establish the effect in traditional classical conditioning experiments, Rescorla's (1977) recent experiments have been successful. Second-order conditioning has also been shown for taste aversion learning. P. J. Best, Best, and Mickley (1973) paired a taste cue with a visual cue previously made aversive through contingent illness. The taste was subsequently avoided. Bond and Harland (1975) used a similar procedure, but employed only tastes as stimuli; they also obtained second-order conditioning.

Summary

The ways in which information is obtained and processed could potentially have revealed qualitative as well as quantitative differences between taste aversion and traditional learning. For example, had blocking, learned irrelevance, and conditioned inhibition not been found to occur within taste aversion paradigms, a good case could have been made for the necessity of using different basic principles to describe the learning of taste aversions. Nevertheless, the data appear to show that in every respect the acquisition and manipulation of information are quite similar for taste aversion and traditional learning.

Age Effects

Several experimenters who used a taste aversion paradigm have reported learning in rat pups (Ader & Peck, 1977; Galef & Sherry, 1973; Grote & Brown, 1971; Klein, Mikulka, Domato, & Hallstead, 1977; Rudy & Cheatle, 1977). One trial is often all that is necessary for learning to occur (Ader & Peck, 1977; Galef & Sherry, 1973; Grote & Brown, 1971;

Rudy & Cheatle, 1977). This seems inconsistent with results obtained in traditional learning in which acquisition of passive avoidance tasks, a paradigm similar in many ways to the taste aversion paradigm, is worse in weanling than in adult rats (Brunner, 1969; Campbell & Coulter, 1976; Riccio, Rohrbaugh, & Hodges, 1968). However, it would be premature to conclude, based on this evidence alone, that weanling rats learn taste aversions as easily as adults, but learn passive avoidance tasks much worse than adults.

Although young rats do learn taste aversions, it may not be as easy for them to acquire aversions as it is for adult rats (Klein, Domato, Hallstead, Stephens, & Mikulka, 1975). On the traditional learning paradigm side of the question, Feigley and Spear (1970) reported an experiment in which they showed that weanling rats do as well as adults at a passive avoidance task if the young rats are trained in an apparatus proportional to their body size. The question of the comparative conditionability of weanling and adult rats in standard and taste aversion learning paradigms is far from settled.

Similarly, it first appeared that rat pups, unlike adults, show little long-term retention of all types of tasks (Campbell & Coulter, 1976; Feigley & Spear, 1970) except taste aversions (Ader & Peck, 1977; Klein et al., 1977). However, a recent article by Coulter, Collier, and Campbell (1976) has shown that if a conditioned emotional response paradigm is used in which the animal's size is irrelevant to the performance of the task (as may be the case with taste aversion learning), long-term retention is found even when the animals are trained at a much earlier age (17 days) than was previously thought possible for traditional conditioning. The rats in Coulter et al.'s studies were at least as young as those used in the taste aversion retention experiments.

Conclusions

A detailed comparison of taste aversion data with results from more standard paradigms is significant not for the number of differences revealed between the two research areas, but for the number of similarities. In virtually all cases the same principles are sufficient for describing taste aversion and traditional learning data. In addition to the qualitative similarities, the two research areas are also often quantitatively similar. To take a simple example, taste aversions are extinguished by presenting the CS without the US, as in a standard classical conditioning experiment; similar principles apply for both paradigms. Further, several and sometimes many trials are needed for extinction of a taste aversion to occur, numbers that apply as readily to tasks learned in traditional paradigms.

Some qualifications are in order, however. Two problems of comparing taste aversion with traditional learning were stated in the Introduction. These were, first, defining the laws of learning and, second, specifying what constituted a deviation from one of these laws. After reviewing the literature, a third difficulty became apparent. The research discussed in the section entitled Traditional Learning is not homogeneous. Within that category are many examples of what Seligman (1970; Seligman & Hager, 1972) would call prepared and contraprepared learning. In addition, much of traditional learning also involves feeding or interoceptive stimuli. The characteristics of taste aversion learning that are said to be unique appear frequently to be better described as characteristics of prepared or feeding behavior. Any comparison of taste aversion and traditional learning should take these factors into account. Nevertheless, this review has demonstrated that at the level of the whole organism there is little basis at this time for a claim that there are qualitative differences between taste aversion learning and traditional learning, as best demonstrated by the sections entitled Obtaining and Processing Information and Generalization of the CS.

At several points in this article the data suggested that taste aversion learning shows certain quantitative differences from the learning of most other traditional tasks. Included among these are differences concerning rapidity of acquisition and long-delay

learning. Although one might say that these are only parametric peculiarities, they are important determinants of behavior, which may be evolutionarily determined, and they should not be ignored. It was also noted that the fact that taste aversions are acquired in one trial with extremely long delays is such a large parametric difference that in this instance the qualitative–quantitative distinction appears inappropriate.

To be able to describe and predict what occurs in taste aversion learning, it is necessary to have a full understanding of each species' feeding behavior under natural conditions. Otherwise, one would be unlikely to predict that, for example, rats will more easily associate tastes than exteroceptive stimuli with illness. The unusual quantitative properties of taste aversion learning mentioned above are in accord with what is adaptive for the organism (Kalat, 1977). Credit must be given to those who are calling for more examination of laws of learning and behavior with regard to these laws' adaptiveness for a species' ecological niche (e.g., Bolles, 1973; Garcia et al., 1977; Hinde, 1973; Lockard, 1971; Rozin, 1976, 1977; Schwartz, 1974; Seligman & Hager, 1972).

Many of these authors have in addition disparaged some of the more traditional learning theorists, who they claim stated that any stimulus is equally associable with any response and that laws of learning are the same across all species. However, the traditional theorists very often did realize that there are differences between species, but thought that the similarities between species are the more interesting and more important phenomena to study in developing a science of behavior (see, e.g., Skinner, 1959, pp. 374–375). Other psychologists unfortunately too often interpreted this belief as a theoretical assumption of more similarity than the data ever indicated.

Recent emphasis on discoveries of diversity and complexity in the characteristics of learning does not mean that an attempt must now be made to describe new principles and laws. Instead, in at least some cases the traditional ones should be made flexible enough to deal successfully with the species- and task-specific characteristics that are more prevalent than previously recognized (see Krane & Wagner, 1975; Rozin, 1977; and Seligman, 1973, for similar views). Without a system of general laws we might find ourselves in an overwhelming jungle of unique abilities and behaviors. In addition, a hypothesis of general laws of learning is not necessarily unreasonable from an evolutionary standpoint. Since every species has been shaped by evolution and since certain selection pressures are common to us all, species-general behaviors could result (Lockard, 1971; Rozin & Kalat, 1971). Further, phyletic closeness (Lockard, 1971), economy of neural wiring of the organism (Rozin & Kalat, 1971), or the uniformity of rules of future prediction (Revusky, 1977d) may give rise to similar processes of learning in different species and in different situations.

The effects that taste aversion experiments have had on preexisting psychological theory are consistent with Kuhn's (1962) description of the progress of scientific revolutions. Anomalous taste aversion data challenged traditional theory (Rozin, 1977). These data were different enough to impel some psychologists (e.g., Seligman, 1970) to suggest that many of the standard laws would not apply. Others (e.g., Rozin & Kalat, 1971) advocated the replacement of the old paradigm, general laws of learning, with a new one, a principle of evolutionary adaptiveness. A thorough comparison of the taste aversion and traditional learning data now reveals them not to be so discrepant after all. Yet without the emphasis by various learning theorists on the anomalous character of the taste aversion results, it is doubtful whether the somewhat unusual aspects of these data would ever have been noticed (see also Boring, 1929).

After the proposal of general laws of learning and a recent swing to laws that are unique and specialized, a less extreme swing, back to the eclectic middle ground, is due. This view recognizes the existence and utility of general laws of learning, but it also recognizes the necessity of acknowledging and investigating the dissimilarities in the learning of different species and in the learning of dif-

ferent tasks. Otherwise we are likely to assume generality where none exists. The research on taste aversion has taught us at least this much.

Determinacy of Common Factors: A Nontechnical Review

Roderick P. McDonald
Ontario Institute for Studies in Education
Toronto, Canada

Stanley A. Mulaik
Georgia Institute of Technology

Most previous accounts of the factor-score indeterminacy problem have failed to give empirical meaning to alternative factor variables. An empirical interpretation of alternative factor variables is developed in terms of alternative tests of infinite length that include a given core set of variables as a subtest. We show that if the core set can be given the same factor loadings on a factor when analyzed alone or in the context of an infinite domain of variables, then there is just one factor variable in the domain that is a possible factor variable of the core set. If consistent factor loadings cannot be found, there is no factor variable in the domain that is a possible factor of the core set. In the latter case, alternative subdomains of variables may contain alternative possible factors of the core set.

Psychologists who use factor analysis undoubtedly know that the common factor model is considered to have special problems that arise from the indeterminacy of its factor scores. Nevertheless, the actual nature of these special problems is almost certainly not widely understood.

Recent publications (Green, 1976; McDonald, 1974, 1977; Mulaik, 1972, 1976; Mulaik & McDonald, 1978; Schönemann, 1971; Schönemann & Steiger, 1976; Schönemann & Wang, 1972) have dealt with the problem of factor-score indeterminacy in a highly technical manner. Consequently, the psychologist who uses factor analytic techniques occasionally in his research may be confused about the conflicting views that have been expressed on this problem and its meaning for his own research, and he may be unaware of a developing consensus about the problem and its implications.

The objects of this article are first to give a relatively nonmathematical account of factor-score indeterminacy, second to review the major recent discussions of it, and third to offer a resolution of the conflicting views that have arisen, while making clear the implications of factor-score indeterminacy for the definition of common factors and for the practice of factor analytic research.

Factor-score indeterminacy refers to the fact that the common and unique factor scores in the common factor model are not uniquely determined by the observed variables whose correlations they explain, since in general the multiple correlation between a common or unique factor and the observed variables is less than unity.

This fact has sometimes been taken to mean that one cannot obtain exact scores on a common factor and that one must therefore settle for regression estimates of them. Such a view is not strictly correct, as it is quite possible to construct numbers that behave precisely like scores on a given common factor. The difficulty is instead that infinitely many sets of such numbers can be constructed, each set in correspondence with a given set of observations. In other words, the factor scores do not have a unique mathematical definition. Given a factor analysis of the observed variables, with factor pattern, factor structure, and factor correlations all determined to one's

satisfaction (i.e., with rotational indeterminacy eliminated), there are still infinitely many random variables that can satisfy the conditions for being a possible factor variable that corresponds to each column of factor loadings, and there need not be a high correlation between two alternative possible factor variables.

The observation that factor scores lack a unique mathematical definition has led some writers to conclude that there is something wrong with the common factor model and that we should abandon it in favor of some approximately equivalent model that is not also believed to have something wrong with it. The usual alternative is some version of component theory (e.g., Kaiser, 1970; Schönemann & Steiger, 1976).

On the other hand, many psychologists who use factor analysis would not see any importance in the questions that have been raised about the indeterminacy of factor scores. Essentially, they know very well how seldom they require the assessment of factor scores, and they see no logical connection between questions about factor scores and the widely accepted aim of factor analysis, namely, the interpretation of a common factor in terms of the common attribute of the tests that have high factor loadings on it. (Indeed, so strong is the effect of this practice that some users forget basic theory and come to think of a factor as a profile of factor loadings of tests, not as a score that characterizes a subject.)

It turns out, however, that in exploratory factor analysis as it is usually employed, the range of possible mathematical constructions of a possible factor variable corresponds to a range of possible ambiguity in the interpretation of a common factor. Moreover, this ambiguity cannot be avoided by approximating the model with components. In its broader implications, factor-score indeterminacy does not merely concern the problem of obtaining a score, or the problem of obtaining too many scores, that might be the score of an individual on a common factor. Rather, it concerns the inability of a finite set of observed variables in an exploratory factor analysis to determine unambiguously what attribute of the individuals the factor variable represents. This is important, as one will see, because factor analysis has commonly been treated as a theory-generating device; that is, it has been treated as a device for the post facto discovery of the psychological concepts that explain the correlations of the variables one has chosen to measure.

In the following discussion, we simplify the issues by concentrating on the special case of common factor analysis in which there is just one general factor (the Spearman case). In this special case, the mathematics can be kept simple, and there is no possible confusion between the indeterminacy of factor scores and the indeterminacy of factor loadings due to rotation. For the most part, the corresponding results for multiple factors are straightforward analogues.

The Basic Results

We begin by considering a vector of n random variables, $\mathbf{y}' = (Y_1, \ldots, Y_n)$, each of which has a mean of zero and a standard deviation of unity. In most applications one can think of $\mathbf{y}$ as corresponding to the scores on n tests obtained by a person randomly drawn from an infinite population $\mathcal{P}$.

A very simple and sufficient definition of the general factor model is to postulate that there exists a random variable X (an additional variable defined on the set of persons in $\mathcal{P}$) such that the n (linear) regression estimators of $Y_1, \ldots, Y_n$ from X have mutually uncorrelated residuals. This defines the model completely. We express this statement symbolically by writing

$$\hat{\mathbf{y}} = \mathbf{f}X, \tag{1}$$

where $\hat{\mathbf{y}}' = (\hat{Y}_1, \ldots, \hat{Y}_n)$, $\mathbf{f}' = (f_1, \ldots, f_n)$, and $\hat{Y}_j$ is the regression estimator of Y_j from X with slope f_j. The vector $\mathbf{e}$ of residuals is then defined by

$$\mathbf{e} = \mathbf{y} - \hat{\mathbf{y}}, \tag{2}$$

and by definition the residuals are uncorrelated with X. It then follows that the $(n \times n)$ correlation matrix $\mathbf{y}$ takes the form

$$\mathbf{R} = \mathbf{f}\mathbf{f}' + \mathbf{U}, \tag{3}$$

where by the assumption of uncorrelated residuals,

$$\mathbf{U} = \text{diag}\,(1 - f_1^2, \ldots, 1 - f_n^2). \tag{4}$$

In conventional terminology, the regression weights f_j are *factor loadings*. These are also the correlations of the tests with the general factor. The residual variances $u_{jj} = 1 - f_j^2$ are the *unique variances*.

In applications of the model, one attempts to fit the hypothesis in Equation 3 to a sample correlation matrix. If the fit is acceptable, one interprets the general factor X as whatever attribute of the persons in $\mathcal{P}$ seems to be common to the tests.

It is reasonable to suppose that all unique variances are greater than zero, that is, no test is perfectly correlated with the factor, if only because of errors of measurement. If these assumptions are true and the number of tests is finite, the multiple correlation of the common factor X with the observed variables is strictly less than unity. The regression estimator of X from $\mathbf{y}$ is given by

$$\hat{X} = \mathbf{f}'\mathbf{R}^{-1}\mathbf{y}, \tag{5}$$

and the corresponding squared multiple correlation ρ^2 of X and $\hat{X}$ is given by

$$\rho^2 = \mathbf{f}'\mathbf{R}^{-1}\mathbf{f}. \tag{6}$$

Because of Equation 4, Equation 5 can be expressed as

$$\hat{X} = \frac{1}{g}\sum_{j=1}^{n} \frac{f_j^2}{1 - f_j^2} Y_j, \tag{7}$$

and Equation 6 can be expressed as

$$\rho^2 = g/g + 1, \tag{8}$$

where

$$g = \sum_{j=1}^{n} [f_j^2/(1 - f_j^2)] \tag{9}$$

(see, e.g., McDonald & Burr, 1967). From the form of Equation 8, if g is finite, ρ^2 is strictly less than unity (since g is strictly less than $g + 1$). If one can conceivably find infinitely many variables with nonzero loadings on X, then in the limit as n approaches infinity, g approaches infinity and

$$\lim_{n\to\infty} \rho^2 = 1 \tag{10}$$

(Piaggio, 1931, 1933). One can think of Equation 8 with Equation 9 as a generalization of the Spearman–Brown formula for the reliability of a test as a function of its length (cf. McDonald & Burr, 1967, p. 392). In effect, one sees that the general factor cannot be determined with perfect reliability by a test battery of finite length. This simple fact is not, however, the problem of factor-score indeterminacy. If it were, one would deal with it in practice by simply admitting that one expects all social science measurements to be imperfect, and one would be satisfied with values of ρ^2 in the general range of acceptable reliability coefficients. These values are ordinarily obtainable in factor analytic studies.

Instead the problem of factor-score indeterminacy as it has been presented is as follows. A necessary and sufficient condition for a random variable X^* (in standard score form) defined over the population $\mathcal{P}$ to have the properties of X in Equations 1–4 is that the correlations of X^* with $Y_1, \ldots, Y_n$ be given by

$$\rho(X^*, Y_j) = f_j, \quad \text{where } j = 1, \ldots, n. \tag{11}$$

If a standardized random variable X^* has the required correlation with $\mathbf{y}$, one says that it is a possible factor variable of $\mathbf{y}$. There are infinitely many such factor variables definable over $\mathcal{P}$ (Guttman, 1955; McDonald, 1974; Mulaik, 1976). (Note also that $\hat{X}$ is not itself a possible factor variable of $\mathbf{y}$.)

If X_1 and X_2 are two standardized random variables that have the required correlations with $\mathbf{y}$, one can obtain bounds on the correlation ρ_{12} between them by showing that the partial correlation of X_1 and X_2, with $Y_1, \ldots, Y_n$ partialed out, is given by

$$\rho_{12\cdot\mathbf{y}} = \rho_{12} - \rho^2/1 - \rho^2. \tag{12}$$

Since this partial correlation must lie between -1 and $+1$, it follows that

$$2\rho^2 - 1 \leq \rho_{12} \leq 1, \tag{13}$$

where ρ^2 is given by Equation 8 as before. This result was first given by Guttman (1955) in the more general case of multiple factors, using a different line of argument.

Another necessary and sufficient condition for X^* to have the properties of the general

factor X in Equations 1–4 is that

$$X^* = \hat{X} + D^*, \qquad (14)$$

where $\hat{X}$ is the regression estimator given by Equation 7 and D^* is any random variable defined over the population that has the properties of a residual of X about $\hat{X}$, that is, any random variable that has variance $1 - \rho^2$ and correlations

$$\rho(D^*, Y_j) = 0, \quad \text{where } j = 1, \ldots, n. \qquad (15)$$

This result was first given by Spearman (1922). It was also obtained by Heywood (1931) rather more rigorously and, in the general case of multiple factors, by Kestelman (1952) and Guttman (1955). (The latter was the first to establish that the condition is necessary as well as sufficient.)

That there is a problem of factor-score indeterminacy, beyond the mere fact of imprecision of the estimates given by $\hat{X}$, is first noticed when one observes that since the range of possible values of ρ^2 is from zero to unity, the range of possible minimum values of ρ_{12} is from minus unity to unity; and if ρ is less than $1/(2)^{\frac{1}{2}}$, then ρ_{12} is possibly zero. That is, if the correlation between the estimator and a possible factor variable is less than .707, the correlation between two such possible factor variables can be as low as zero. It is not immediately obvious what empirical interpretation to place on this fact, however.

Interpretations of Factor-Score Indeterminacy

Guttman (1955), having introduced the bounds (Inequality 13) and having noted in particular that one requires $\rho^2 > .71$ if the lower bound on ρ_{12} is to be positive, set out its implications for the scientific meaning of factor analysis in the following remarks:

It appears from the relation of $[2\rho^2 - 1]$ to $[\rho^2]$ (for each intended factor) that the predictability of factors from [y] is not merely a practical problem. If $[2\rho^2 - 1]$ is low, it raises the question of what it is that is being estimated in the first place; instead of only *one* 'primary' trait there are many widely different variables associated with a given profile of loadings. . . . If more direct observations on factor scores cannot be made than statistical analysis of R and [y], the Spearman–Thurstone approach may have to be discarded for lack of determinacy of its factor scores. (p. 79)

Similarly one finds:

The widespread practice of trying to name or attach meaning to factors merely by studying factor *loadings* is clearly suspect if the same loadings can be derived equally well from radically different sets of factor scores. (Guttman, 1957, p. 149).

Schönemann and Wang (1972) pointed out that in estimating the factor model on the Lawley–Rao basis (which is usually employed in fitting the unrestricted model by maximum likelihood), instead of retaining factors corresponding to eigenvalues greater than unity, one would have to retain only factors with eigenvalues greater than two

if one were to insist on factors which are better determined than a set of standardized random numbers are (in the sense that the scores on factor $[X_1]$ can be predicted better from scores on its equivalent twin $[X_2]$ than from a set of random numbers. (Schönemann & Wang, 1972, p. 69)

They then proceeded to show that in empirical studies, some factors that are needed to explain the correlations do not have acceptable—apparently meaning positive—lower bounds to the correlation between possible alternative factors, and they claimed that this appears to create a dilemma for the user of the model.

We notice a difficulty in coming to grips with these interpretations of factor-score indeterminacy. As stated above, given at least the existence of errors of measurement, no test of finite length will be perfectly correlated with the factor, hence no test of finite length will have the properties of a common factor variable. It is not enough to be told that attaching meanings to factors on the basis of factor loadings is "clearly" rendered suspect by the existence of alternative possible factor variables. One needs also to be told how to find at least two distinct possible factor variables and on what grounds one might place distinct interpretations on them. Instead, Guttman (1955) showed only that one can construct alternative factor variables in infinitely many ways by adding to a regression estimate $\hat{X}$ a value of a random variable D^*, as in Equations 14 and 15, defined "by throwing dice or turning a roulette wheel" (p. 70). More precisely, to construct a possible factor score for any person randomly drawn from the defined population $\mathcal{P}$, one makes one

throw of the dice, or turn of the roulette wheel (or generates one number by means of a random number generator), and arbitrarily associates the additional random number D^* so obtained with the scores of the randomly drawn person. Schönemann and Wang (1972) suggested similar procedures for constructing possible factor scores and remarked that since infinitely many different sets of such numbers can be computed, they need not be estimated.

However, although such computational procedures do indeed yield mathematically admissible alternative factor variables, the solutions so obtained can hardly be regarded as measurements of empirical properties of persons in the population $\mathcal{P}$. Measurement constitutes the assignment of numbers to objects in such a way as to represent empirical relationships by numerical relationships. It is hard to see how assigning artificially generated random numbers to persons in the population can represent empirical relationships (of order, say) among these persons. Thus, these alternative factor variables lack empirical significance and as such cannot be regarded as lending themselves to distinct interpretations of the factor. Hence the argument that factor indeterminacy renders the interpretation of factor loadings suspect is incomplete. Therefore, it is understandable if the typical user of factor analysis chooses to disregard this argument.

McDonald (1974) sought to offer an escape from the mathematical dilemma pointed out by Schönemann and Wang (1972). Based on a general mathematical theorem about the construction of and relationship between all possible factor variables, McDonald's discussion consisted essentially of two main arguments.

The first of these was a demonstration that the correlation between two distinct simulations of a factor variable, using independent residual variables D^* in Equation 14 (generated by using the artificial devices suggested by Guttman, 1955, and by Schönemann and Wang, 1972), is ρ^2. Two implications of this are (a) that ρ^2 is the correlation between any possible factor of y, defined (without simulation) over $\mathcal{P}$, and any simulation of it created by the devices recommended and (b) that ρ^2 is the correlation between two independent simulations of a possible factor of y made by independent investigators.

The second argument amounted to a declaration that for consistency one must adopt the convention that the common factor be thought of as uniquely defined, though unobservable; hence the (minimum) correlation between alternative possible factor variables cannot serve as a measure of the indeterminacy of the common factor, since the distinct values of these alternatives for a given person in $\mathcal{P}$ cannot both be the unique but unknown value of his factor.

The first of McDonald's arguments is correct, but is not, as it turns out, particularly useful. The second, it can now be shown, is ambiguous and incomplete and seemingly has proved unconvincing.

Mulaik (1976) rejected McDonald's second argument, claiming that Guttman's lower bound represents a measure of the extent of possible disagreement between two investigators about the nature of a factor. Mulaik's argument assumes that two investigators might actually find two distinct empirical measures, either of which has the properties of the common factor variable. Further, the empirical measures might be imperfectly correlated, and their test contents might give conflicting interpretations of the factor (presumably whether or not these were consistent with the contents of the remaining n tests). Mulaik further argued that in typical applications factor analysts will have at most only a few alternative empirical interpretations of a factor and that the expected correlation between pairs of alternative factor variables (across a universe of such pairs, randomly selected) will be greater than or equal to ρ^2 in Equation 6.

Green (1976) offered a generally conciliatory conclusion on what he described as the "factor indeterminacy controversy," suggesting that all possible factor variables are equally true and that both ρ^2 and $2\rho^2 - 1$ serve as measures of factor-score indeterminacy.

With the exception of remarks in Mulaik (1976), what all of these discussions have in common is a failure to relate the problem described to any discernible realities of factor analytic practice.

It turns out that although it is not true that

different investigators might construct different empirical measures of finite length that satisfy Inequality 13 and hence are possible factor variables, there are conditions under which they might construct the beginnings of sequences of variables (each of which contains at least some error of measurement) that would in the limit yield tests of infinite length that satisfy Inequality 13. This fact and its consequences form the topic of the next section.

Determinacy of Common Factors in a Behavior Domain

One way to give empirical meaning to alternative possible common factor variables has been shown by Mulaik and McDonald (1978). They considered the possible factors of two sets of variables obtained by augmenting a core set of n variables (*marker* variables for a factor, one might say) with different sets of additional variables, subject only to the condition that each augmented set continue to satisfy a common factor model consistent with the model for the core set. They discussed what one might call alternative tests of infinite length, developed from the given core set and each uniquely determining a factor variable. They gave conditions under which these tests of infinite length will determine the same factor variable. If these conditions are not satisfied, the tests may determine distinct factor variables whose correlations in the limit are subject only to the Guttman bounds (Inequality 13). See also McDonald (1977).

Here we give a simpler treatment of the problem, directly based on behavior domain theory. Following Guttman (1957), we suppose that the n variables $Y_1, \ldots, Y_n$ of the section entitled The Basic Results are drawn from a set of $n + m$ empirical variables $Y_1, \ldots, Y_n$ and $Y_{n+1}, \ldots, Y_{n+m}$, a *universe of content* or *behavior domain* that is defined in advance of any statistical analysis.

An ambiguity concerning the possible alternative factor variables of $Y_1, \ldots, Y_n$ is removed by supposing that $f_1, \ldots, f_n$ are fixed, known values. In practice, this means that one must have at least three variables in the core, whose correlations then determine the factor loadings uniquely. (In the multiple-factor counterpart of these arguments, we would require that the factor loadings be fixed against rotation and known.)

Write

$$\mathbf{y}'_1 = (Y_1, \ldots, Y_n), \quad \mathbf{y}'_2 = (Y_{n+1}, \ldots, Y_{n+m}),$$

and

$$\mathbf{R} = \begin{bmatrix} \mathbf{R}_{11} & \mathbf{R}_{12} \\ \mathbf{R}_{21} & \mathbf{R}_{22} \end{bmatrix} \tag{16}$$

for the joint correlation matrix of $\mathbf{y}_1$ and $\mathbf{y}_2$, partitioned conformably.

One cannot seek to establish any relationship between the possible factor variables of $Y_1, \ldots, Y_n$ and those of the behavior domain, except under the condition that one is able to obtain a joint factor analysis of the $n + m$ variables in which the factor loadings of the first n are the same as when the first n is factored without the further m. If this condition is satisfied, we say that the core and the domain have consistent loadings. If the core and the domain do not have consistent loadings, there is no more reason to seek a relationship between their possible factors than to seek a relationship between two of the multiple factors in an orthogonal multiple factor analysis. Although the effect of adding more variables may be to add further common factors, so that, say, there are r common factors altogether, the requirement of consistent loadings is that one must be able to fit the model and choose a rotation in such a way that the factor loadings of the n core variables are unaltered in the context of the additional m variables. It can hence be seen that the core and the domain are consistent in this sense if and only if the factor solution for the domain is of the form

$$\begin{aligned} &\begin{bmatrix} \mathbf{R}_{11} & \mathbf{R}_{12} \\ \mathbf{R}_{21} & \mathbf{R}_{22} \end{bmatrix} \\ &= \begin{bmatrix} \mathbf{f}_1 & \mathbf{G}_1 \\ \mathbf{f}_2 & \mathbf{G}_2 \end{bmatrix} \begin{bmatrix} \mathbf{f}'_1 & \mathbf{f}'_2 \\ \mathbf{G}'_1 & \mathbf{G}'_2 \end{bmatrix} + \begin{bmatrix} \mathbf{U}_1 & \\ & \mathbf{U}_2 \end{bmatrix} \\ &= \begin{bmatrix} \mathbf{f}_1\mathbf{f}'_1 + \mathbf{D} + \mathbf{U}_1 & \mathbf{f}_1\mathbf{f}'_2 + \mathbf{G}_1\mathbf{G}'_2 \\ \mathbf{f}_2\mathbf{f}'_1 + \mathbf{G}_2\mathbf{G}'_1 & \mathbf{f}_2\mathbf{f}'_2 + \mathbf{G}_2\mathbf{G}'_2 + \mathbf{U}_2 \end{bmatrix}, \end{aligned} \tag{17}$$

where

$$\mathbf{G}_1\mathbf{G}'_1 = \mathbf{D}, \tag{18}$$

a diagonal matrix with nonnegative diagonal terms, and

$$\mathbf{U}_1 = \mathbf{U} - \mathbf{D}, \qquad (19)$$

which also contains nonnegative diagonal terms and where $\mathbf{U}$ is the original unique variance matrix given by Equation 4. What this means is that the effect of adding variables may be to redefine some of the unique variance of one or more components of $\mathbf{y}_1$ as common variance, that is, variance in common with that of components of $\mathbf{y}_2$. The loadings in $\mathbf{G}_1$, with the property defined in Equation 18, take care of this possibility, but do not account for any correlation between components of $\mathbf{y}_1$. The loadings in $\mathbf{G}_2$ account for some of the correlation between components of $\mathbf{y}_2$ and, together with $\mathbf{G}_1$, for any correlation between components of $\mathbf{y}_1$ and components of $\mathbf{y}_2$ that is not accounted for by the original general factor.

One now recognizes a simple result of fundamental importance: A possible common factor variable of the domain is a possible general factor of the core factored separately, if and only if the domain and the core have consistent loadings. To see this, note that if one has the structure of Equation 17 with Equation 18 and 19, one can write the corresponding factor model in the form

$$\begin{bmatrix} \mathbf{y}_1 \\ \mathbf{y}_2 \end{bmatrix} = \begin{bmatrix} \mathbf{f}_1 & \mathbf{G}_1 \\ \mathbf{f}_2 & \mathbf{G}_2 \end{bmatrix} \begin{bmatrix} X \\ \mathbf{z} \end{bmatrix} + \begin{bmatrix} \mathbf{e}_1 \\ \mathbf{e}_2 \end{bmatrix}, \qquad (20)$$

where $\mathbf{z}$ is a vector of $r - 1$ additional common factor variables and the residuals $\mathbf{e}_1$ and $\mathbf{e}_2$ have covariances given by $\mathbf{U}_1$ and $\mathbf{U}_2$. Then if $\mathbf{y}_2$ is deleted, Equation 20 become

$$\mathbf{y}_1 = \mathbf{f}_1 X + \mathbf{G}_1 \mathbf{z} + \mathbf{e}_1 = \mathbf{f}_1 X + \mathbf{e}, \qquad (21)$$

where $\mathbf{e}$ is given by Equation 2, since $\mathbf{G}_1\mathbf{z} + \mathbf{e}_1$ has the covariance matrix $\mathbf{U} = \mathbf{U}_1 + \mathbf{D}$ and behaves just like the original residual. Conversely, if there is a common factor of the joint set that is a possible general factor of the core set (possibly with additional common factors), then it satisfies Equation 11, and so it must be possible to express the joint common factor pattern in the required form. This completes the proof of the stated result

Further, by an obvious extension of the well-known result (Equation 10) given by Piaggio (1931, 1933), it follows that if m, the number of additional variables in the domain, is infinitely large, then the possible first factor is uniquely determined by the $n + m$ variables that constitute the domain, since its multiple correlation with them is unity. (This assumes that a nonzero proportion of the components of $\mathbf{f}_2$ is strictly greater than zero.)

Thus one finds that if the domain factor pattern is not consistent with that of the core, that is, if it cannot take the form of Equation 17 with Equations 18 and 19 and the conditions on them, then there is no possible common factor variable of the domain that is also a possible general factor variable of the core set. If the joint factor pattern is consistent with the core set, so that possible factor variables of the domain and of the core set can be defined on the same basis, and if the additional variables of the domain have nonzero loadings on the factor that is marked by the core, there is one and only one factor variable in the domain that is a possible factor of the core set. In this case, the factor loadings of the core set mark a unique factor variable in the domain, which is determined as precisely as one pleases by the addition of further variables with nonzero loadings. This confirms the conclusion given by McDonald (1974) on purely formal grounds. In other words, there are not infinitely many possible alternative factor variables in a behavior domain that correspond to the profile of loadings of a given core set of variables from the domain. Either there is just one factor variable in the domain consistent with the core or there is no such factor variable.

If there is a factor variable of the domain that is consistent with the core, it can be shown that the squared correlation between it and the estimator given by Equation 5 is ρ^2 (given by Equation 6), as one would expect. McDonald (1974) has shown that the index ρ^2 as a measure of the determinacy of factor scores does not yield any of the dilemmas associated with the lower bound, $2\rho^2 - 1$.

However, before one concludes that the problem of factor-score indeterminacy has just been eliminated, one must examine the consistency conditions more closely. Essentially, the requirement is that if, in traditional terminology, one "extracts" the first factor,

then the first residual matrix,

$$R^{(1)} = \begin{bmatrix} R_{11} & R_{12} \\ R_{21} & R_{22} \end{bmatrix} - \begin{bmatrix} f_1f'_1 & f_1f'_2 \\ f_2f'_1 & f_2f'_2 \end{bmatrix}, \quad (22)$$

must be at least nonnegative definite, that is, a possible covariance matrix of real variables, so that it can be factored in its turn in terms of real factor loadings and nonnegative unique variances. It is important to recognize that there is no reason whatsoever to suppose that this condition will always, or even usually, be fulfilled in practice. Actually, it is a generalized counterpart of the condition that there be no Heywood variables (i.e., variables with negative unique variance). One knows that the condition has been violated if one attempts to add variables to a core, prescribing a consistent analysis, and one obtains a Heywood case. But generally one will not know whether the domain contains variables that, if one were to add them to the core, would violate the required condition.

Mulaik and McDonald (1978) have shown that if a behavior domain does not satisfy conditions similar to Equations 17–19, then such a domain can possibly be divided into overlapping subdomains, all containing the core set as a subset and possessing disjoint sets of factor variables with possible correlations that are only bounded as in Inequality 13. That is, if there is no factor variable in the domain that is a possible factor variable of the core set, there may be factor variables of subdomains that are distinct possible factors of the core set, with correlations anywhere between $2\rho^2 - 1$ and 1. As a consequence, if two investigators take a common core of variables as markers for a factor and independently draw variables from such a domain, not by a sampling rule but by merely augmenting the core set subject to the satisfaction of the general factor model, they can define two distinct tests of infinite length, containing distinct variables that lend themselves to distinct interpretations. Only when the two sets of augmenting variables are merged will one discover that the domain does not have a basis consistent with the core and hence has no factor variable that is a possible factor of the core.

This implies also that one certainly cannot use the factor model to define a behavior domain; that is, a behavior domain is not uniquely defined by choosing a core set of variables that fits the common factor model and then saying that the domain consists of all variables that, jointly with the core set, fit the common factor model with the same number of factors.

Thus, we have arrived at an empirical treatment of the significance of factor indeterminacy. It is a variant of results given by Mulaik & McDonald (1978) and McDonald (1977). If a behavior domain can be factored so that one of its common factors has the same loadings on a core set of variables as when the latter are factored separately, it is then meaningful to consider the relationship between the possible factors of the core and the possible factors of the behavior domain. In such a case, the loadings of the core set uniquely mark a factor variable in the domain, and the addition of further variables with nonzero loadings on the factor will determine it as precisely as one pleases, ultimately yielding an infinite sequence of variables that determines the factor exactly. If the behavior domain cannot be factored consistently with the core, there is no factor variable in the domain that is a general factor of the core set, but there may be many factor variables of subdomains that are distinct alternative general factor variables of the core set. Incompatible sets of variables added to the core set may yield distinct tests of infinite length, defining distinct factor variables and susceptible to distinct interpretations on the basis of their profiles of factor loadings on the distinct tests.

These observations eliminate the paradoxes to be found in the previous purely mathematical treatments of the topic, since the condition under which two possible tests of infinite length, obtained by augmenting a core set, can be correlated zero when each is estimated with $\rho = .707$ is the condition that a corresponding factor in the domain taken as a whole does not exist. If a factor in the domain is defined by the loadings of the core tests, it is defined uniquely.

However, these results do not define away the problem of factor indeterminacy. Rather, they point to its significance for the user of the model. Most users of factor analysis

employ the model in an exploratory fashion. In doing so, they do not begin with a set of relatively clear psychological concepts and then select variables for their study that on the basis of theory should contain or be determined by these concepts. Nor, on the other hand, do they begin with a clearly defined behavior domain (from which all investigators would recognize equally how to develop representative measures) and then select from it a reasonable number of variables to represent the domain in a balanced fashion. Instead, they begin with a number of variables in which they are interested, which might or might not correspond to a general preconception of a behavior domain of tests that "resemble" the tests chosen. Their hope is that when these variables are subjected to a factor analysis, the psychological attributes that determine the correlations among the variables will reveal themselves. Thus, exploratory factor analysis is typically employed to generate a theory rather than to test a theory. It is noticeable that in many such applications the user appears quite satisfied with the results. The problem remains, however, of a range of ambiguity with respect to the ways in which the results may be extended by the use of further variables to measure the discovered attribute more precisely.

If the variables have been selected on the basis of certain common attributes defined in advance, there is no uncertainty as to the interpretation of a factor found common to those variables and no uncertainty as to the further variables one would expect to be associated with the same factor. But in the absence of an agreed domain of variables based on prespecified common attributes, two investigators may seize upon distinct sets of common attributes and proceed to build distinct extended batteries of variables on the basis of the same core set, in terms of these distinct attributes. Ultimately, in principle, they can create two distinct test batteries of infinite length, built on the same original test and corresponding to two distinct attributes and to two distinct random variables, either of which might have been the common factor of the original variables. It is factor indeterminacy that supplies a mathematical latitude for such sets of alternative common attributes to be found. This does not mean that they will inevitably be found in practice. It means only that such possibilities exist. It remains for appropriate empirical work, using merged variables, augmented sets, and extension procedures (see McDonald, 1978), to establish how serious these problems are in practice.

What this analysis reveals, essentially, is that it may be naive to use exploratory factor analysis to generate theory out of an ill-defined domain of variables. The danger is that the factor structure of the entire domain may not be remotely consistent with the factor structure of its subdomains.

However, it must be pointed out that these problems of the common factor model do not, as is sometimes supposed, constitute grounds for using alternative modes of analysis such as component theory. McDonald (1975) has discussed some aspects of this choice. Here one recognizes that if one worries about the relationship of factor-score estimates to the variables being estimated, it is because one is able, under certain conditions, to define the variables being estimated on the basis of a behavior domain that fits the common factor model consistently with the given variables. To show that component scores do not have an indeterminacy problem, as studied here, one must show that the component score of a core set of variables uniquely determines a corresponding component score in an infinite domain from which the core set has been drawn. But one knows immediately that this cannot be true. Even if one could find a way to define consistent bases for the core and the domain, and this seems unlikely, the domain component scores would contain error parts and specific parts that would be uncorrelated with variables in the core. Thus, it seems that mathematical arguments (e.g., Schönemann and Steiger, 1976) that favorably contrast component theories, whether principal components, components of images, or other components, with the common factor model cannot be accepted until they are reformulated in terms of behavior domains and in terms of the relation of core components to domain components. It seems unlikely that core components can be shown to yield better representations of components of interest in a

behavior domain than we have in common factor estimates. (See McDonald, 1977, for a more extended account of this question.)

The implications of factor indeterminacy also render suspect the frequently used technique of including sets of marker variables in distinct sets of additional variables, in the hope of determining whether the same factors are to be found in these distinct sets. It is supposed that if the marker variables have the same loadings on a common factor in each of these sets, this is evidence that the same factor variable has turned up in each of these sets. But this need not be so. The marker variables may be associated with different factor variables when embedded within the contexts of different sets of additional variables. The only way to be sure that the same factors are common across the sets is to analyze the marker variables jointly with all the other variables to see if one can obtain consistent loadings. But if this is done, then there is no need for marker variables in the first place.

Because of the close parallels between common factor theory and classical true score theory, factor indeterminacy has important implications for test theory and for test construction in practice. For example, in the construction of homogeneous tests, one might begin with a core set of items that are thought to define a dimension of interest and then add to that core additional items that are factorially consistent with the original core to increase the total-score reliability of the test. If the developer of the tests does this without taking account of the empirical content of the additional items, which in some instances may differ from that of the core variables, he may end up with a test whose total score measures an attribute that is somewhat different from that measured by the original core items. This may happen if the core set of items is selected from one domain with which the core is factorially consistent while the additional items are selected from another domain with which the core items are also factorially consistent. Jointly the union of the two domains of items may not be factorially consistent with the core items, although the domains are factorially consistent separately.

In-Group Bias in the Minimal Intergroup Situation: A Cognitive–Motivational Analysis

Marilynn B. Brewer
University of California, Santa Barbara

Experimental research on intergroup discrimination in favor of one's own group is reviewed in terms of the basis of differentiation between in-group and out-group and in terms of the response measure on which in-group bias is assessed. Results of the research reviewed suggest that (a) factors such as intergroup competition, similarity, and status differentials affect in-group bias indirectly by influencing the salience of distinctions between in-group and out-group, (b) the degree of intergroup differentiation on a particular response dimension is a joint function of the relevance of intergroup distinctions and the favorableness of the in-group's position on that dimension, and (c) the enhancement of in-group bias is more related to increased favoritism toward in-group members than to increased hostility toward out-group members. The implications of these results for positive applications of group identification are discussed.

In 1906, sociologist William Sumner articulated a functionalist approach to the nature of intergroup attitudes in his exposition of the concept of ethnocentrism. The differentiation of peoples into distinct ethnic groups originates, according to Sumner, in context of the "conditions of the struggle for existence." At the individual level, the psychological consequences of this differentiation both reflect and sustain the basic state of conflict between the in-group (or "we-group") and out-groups (or "others-groups"):

> The insiders in a we-group are in a relation of peace, order, law, government, and industry, to each other. Their relation to all outsiders, or others-groups, is one of war and plunder. . . . Sentiments are produced to correspond. Loyalty to the group, sacrifice for it, hatred and contempt for outsiders, brotherhood within, warlikeness without—all grow together, common products of the same situation. (Sumner, 1906, p. 12)

From this perspective, then, attitudinal and perceptual biases in favor of members of one's own group over members of other groups are the product of intergroup competition, serving the dual functions of preserving in-group solidarity and justifying exploitation of out-groups. Presumably also, the greater the intensity of competitive interdependence between groups, the more attraction within the in-group and corresponding hostility toward the other group, whereas low levels of interdependence between groups should be associated with relatively little contrast in attitudes toward members of the in-group and out-group (LeVine & Campbell, 1972).

The functionalist concept of intergroup relations is epitomized in the ambitious field experiment undertaken by Sherif and his colleagues in the context of a boys' summer camp (Sherif, Harvey, White, Hood, & Sherif, 1961). In the fully implemented version of the study, conducted in 1954, two groups of 11-year-old boys were formed in isolation from each other for a period of 8 days before being brought into contact under conditions designed to maximize competition and mutual frustration. The resulting intergroup hostility was documented with anecdotal evidence based on observation of overt behavior, supplemented by controlled measures of sociometric preferences, evaluative trait ratings, and estimates of performance by group members during a competitive task. On each of

these indicators, campers revealed consistent biases favoring members of their own group over members of the competing group. Reductions in bias were not achieved until the nature of the functional relationship between the groups was altered by systematic introduction of "superordinate goals" requiring cooperative interaction.

The Sherif et al. field study is essentially a demonstration rather than a test of the functionalist view of intergroup relations, since its design took for granted that interaction under competitive conditions was prerequisite to the initial development of in-group bias and intergroup hostility. No systematic assessment of attitudes toward in-group and out-group members was made before the intergroup competition phase of the experiment (although changes were documented after competitive pressures had been removed). However, some anecdotal evidence from the 1954 study was provided that indicates that negative reactions to the out-group were present prior to the introduction of structured competition. At the close of the first phase of the experiment, the two groups were first made aware of each other's existence, and at that time the mere knowledge of the presence of the other group was sufficient to generate name-calling and other derogatory commentary from each group directed toward the other (Sherif et al., 1961, p. 95).

The significance of these initial-contact effects has been realized only recently as the phenomena associated with intergroup perception have been reexamined in light of more general cognitive processes by which human beings structure, simplify, and give meaning to their physical and social environment (Hamilton, 1976; Hensley & Duval, 1976; Tajfel, 1969, 1970). From this perspective, any categorization rule that provides a basis for classifying an individual as belonging to one social grouping as distinct from another can be sufficient to produce differentiation of attitudes toward the two groups, in the absence of any initial competitive interdependence. The present review focuses on research directed toward identifying the minimal conditions necessary to generate in-group–out-group discrimination.

Defining the Minimal Intergroup Situation

A number of laboratory studies have attempted to demonstrate the presence of in-group favoritism under conditions in which the independence of outcomes for in-group and out-group is explicitly controlled. Among the earliest of such demonstrations was a study reported by Ferguson and Kelley (1964) in which two groups of three to six members each worked independently on three tasks. Following the interaction group members were asked to rate the quality of the products of both groups separately on a 9-point scale. Mean ratings obtained were significantly biased in the direction of more positive evaluation of subjects' own group's product than of the other group's product, irrespective of any objective differences in output between the two groups.

Subjects in the Ferguson and Kelley experiment had an extensive period of familiarization and personal investment in the outcome, which could have influenced their preference for own-group products. A clearer demonstration of in-group bias is obtained when subjects are asked to evaluate qualities associated with their own and other groups in the absence of any interaction or personal influence on the qualities being rated, as was the case in an experiment by Doise et al. (1972). Subjects in that experiment were divided into "X-type" and "Y-type" groups and were told that the division was based on photograph preferences (although group assignment was actually determined randomly). In the control condition of the experiment, subjects were led to anticipate no further interaction with members of either group, but were asked to describe the other members of their own group and the members of the other group on a series of 19 evaluative trait ratings. Despite the minimal basis for distinction between the two groups, a significant difference in mean favorableness of ratings was obtained in the direction of more positive ratings of members of the subjects' own group. However, in an earlier experiment, Rabbie and Horwitz (1969) found that in a control condition in which subjects were arbitrarily divided into groups labeled *blue* or *green* (with no rationale or further interaction), there were no

significant differences in evaluative trait ratings of individuals in the subjects' own group as opposed to individuals in the other group.

It appears, then, that there are lower limits to the effects of grouping on interpersonal perception but that in-group bias does occur in the absence of explicit competitive interdependence between groups. The absence of implicit competitive orientation in most of these studies, however, is difficult to establish. Indeed, Rabbie and Wilkens (1971) reported that their attempt to create coacting groups under *no-competition* instructional conditions resulted in ratings of perceived competitiveness that were equal to those obtained under explicit *competition* instructions. As Turner (1975) has suggested, the effect of categorization into groups may be mediated by an inherent competition for "positive social identity." Relative to the earlier view of the role of competition in intergroup attitudes, however, this hypothesis reverses the causal ordering in that competition is generated by the differentiation between groups rather than vice versa.

The generation of competitive orientation as a function of in-group–out-group distinctions, in the absence of any functional conflict of interests, is perhaps best illustrated with the paradigm originated by Tajfel and his colleagues for studying intergroup behavior (Tajfel, 1970; Tajfel, Billig, Bundy, & Flament, 1971). The research setting was designed to meet the following criteria for "minimal differentiation" (Tajfel et al., 1971, pp. 153–154): (a) no face-to-face interaction among subjects, within or between groups, (b) anonymity of group membership, (c) absence of any instrumental link between the basis for intergroup categorization and the response measure, and (d) a response measure involving real and significant choices but of no direct utilitarian value to the subject. Following these criteria, subjects in the Tajfel experiments are divided into two groups based supposedly on their responses to an irrelevant judgmental or preference test. After subjects are informed of their own group membership (but in the absence of any contact with or knowledge of other group members), they are given a choice task that involves allocating money between two other subjects in the same experiment. The identity of the other subjects is indicated only by an arbitrary identification number and a label specifying group membership, which can be varied to be the same as that of the subject or to indicate a member of the other group.

The types of choice matrices provided in the Tajfel experiments are illustrated in Table 1, for the case in which one target person is a member of the subject's own group and the other a member of the out-group. Within each matrix, each column represents an alternative allocation of points (worth some specified fractional amount of money) distributed between the two target persons, and the subject is to choose one of the alternatives as the distribution to be made. Matrices are constructed to represent a number of different possible distribution rules that could be applied, including equality (choosing the alternative that comes closest to giving each person the same number of points), maximizing joint outcome (choosing the alternative for which the total number of points is highest), or in-group favoritism (choosing the alternative that affords the in-group member more than the out-group member). For instance, Matrix A in Table 1 pits equality (choices at the middle of the series) against favoritism (choices toward the extreme right), whereas Matrix B varies favoritism (choices at the left), equality (midpoint choices), and joint outcomes (choices at the right).

Across a series of studies that used this allocation task (Billig & Tajfel, 1973; Tajfel & Billig, 1974; Tajfel et al., 1971), Tajfel and his colleagues have found that competitive choices favoring the in-group member tend to dominate over alternative available choice strategies. However, the matrices used in these studies have not been systematically varied to compare favoritism with all possible choice combinations. In particular, choice alternatives that maximize relative gain (i.e., the choice that maximizes the difference between in-group and out-group points in favor of the in-group member) have usually been confounded with alternatives that maximize absolute gain (i.e., the same choice maximizes the number of points that can be provided to the in-group member alone; cf. Matrices A and B in Table 1). Thus, the task structure

itself may have dictated a competitive strategy, in that gain for the in-group could be achieved only at cost to the out-group member. Only one matrix format (Matrix C in Table 1) has been used in which the alternative that maximizes the in-group member's outcome is different from the relative gain choice, and in this case the former is confounded with maximizing joint gain and maximizing the difference in favor of the out-group member.

To test the generality of preference for outcomes that maximize the competitive advantage to the in-group under forced-choice conditions, Brewer and Silver (1978) constructed a series of two-choice matrices to represent all possible pairings of the four alternative distribution rules of interest—equality, joint gain, relative gain, and absolute (in-group) gain (cf. MacCrimmon & Messick, 1976; McClintock, Messick, Kuhlman, & Campos, 1973). The matrices they used are reproduced in Table 2.[1] For each pair of two-choice matrices, the distribution rules that are confounded in the first matrix of the pair are opposed in the second matrix. Thus, assuming consistency of choice preferences across matrices, the pattern of choices for the two matrices in each pair combined discriminates perfectly among the four distribution rules, as indicated by the scoring key associated with each matrix pair in Table 2. Using this forced-choice format, Brewer and Silver found that a majority of subjects who had been divided into groups following an "aesthetic preference" test selected point distributions that maximized relative gain in favor of the in-group over choices that maximized absolute in-group gain or other alternatives. These results confirm that subjects treat in-group–out-group outcomes as competitively interdependent even when such an orientation is not required by the nature of available alternatives.

Sources of Variation in Bias

The research paradigms provided by Sherif et al. (1961) and by Tajfel et al. (1971) represent two extremes of the conditions of intergroup differentiation under which the occurrence of in-group bias may be studied. The Sherif field studies created a high degree of interaction and cooperative interdependence within groups combined with explicit competitive interdependence between groups, whereas the Tajfel laboratory studies involved minimal intragroup relationships and no predetermined functional interdependence between groups. Both types of research yield evidence of the presence of in-group favoritism, but results are not directly comparable for purposes of assessing variations in extent or intensity of such bias. Most of the experimental studies undertaken in this area since 1960 can be viewed as attempts to determine the contribution to in-group bias of various settings in

[1] In the task booklets actually used in the Brewer and Silver (1978) study, the matrices from these pairs were randomly intermixed in order of presentation.

between the extremes represented by the Sherif and Tajfel paradigms.

Table 3 provides a two-way classification of experimental studies published since 1960, in which at least one aspect of the conditions of intergroup differentiation has been systematically varied. Along with a classification of the major independent variables that have been manipulated, the studies listed in Table 3 are categorized according to which dependent variables were assessed of the three most widely used types of measures of in-group bias: (a) subjective ratings of individual group members or of the group membership as a whole on a series of evaluative trait scales, (b) ratings of the quality of group process (e.g., cohesiveness and cooperative atmosphere) or product, and (c) behavioral measures involving resource distribution decisions (e.g., Prisoner's Dilemma Game choices or the Tajfel allocation task). Studies that manipulated more than one independent variable or that included more than one dependent measure are multiply listed in Table 3.

Actual or Anticipated Competition

A number of the studies already reviewed indicated that a competitive reward structure is not a necessary precondition for obtaining significant in-group bias, but whether bias is increased by the presence of explicit conflict of interest between groups remains in question. The early laboratory studies of in-group bias, undertaken in the context of management training groups (Bass & Dunteman, 1963; Blake & Mouton, 1961), compared evaluations of the in-group obtained before and after introduction of a problem-solving competition against one or more other groups and reported consistent increases in positive self-evaluations during the intergroup competition phase.

In a more systematically controlled study of the effects of anticipated and actual competition, Rabbie and Wilkens (1971) divided subjects arbitrarily into pairs of three-person groups and then led both groups either to expect no further interaction or to expect to engage in an interactive task either in competition with the other group or independent of the other group (no competition). (Subjects who initially anticipated no interaction were later placed in the *competition* or *no-competition* conditions.) Ratings of own- and other-group members on six evaluative traits were then obtained from each subject prior to the interaction phase of the experiment and were again obtained from subjects in the competition and no-competition conditions after the interactive task. Before interaction, subjects who anticipated the task gave ratings of in-group members that were significantly higher than those obtained from subjects not expecting interaction, but subjects in all conditions showed equally significant bias in the difference between in-group and out-group ratings. Following interaction, the degree of bias in favor of own-group members increased significantly for subjects in both the competition and no-competition settings (although ratings of group products showed no signifi-

cant in-group bias). Thus, the effect of actual intragroup interaction was to enhance favoritism toward in-group members, but equally so for competitive and independent groups. Similarly, Janssens and Nuttin (1976) found that members of interacting groups overestimated group successes more than did members of noninteracting groups but that groups who engaged in intergroup competition did not overestimate significantly more than groups who coacted independently. However, as was mentioned previously, the success of initial instructions for creating a noncompetitive task structure may be questionable, since a manipulation check in the Rabbie and Wilkens (1971) experiment revealed that *felt* competitiveness was equally high for members of the competition and no-competition groups.

A clearer manipulation of the structure of interdependence between groups is attained when conditions promoting intergroup competition are compared with conditions requiring cooperation between groups. One method for varying this feature of intergroup relations is through the use of instructional sets designed to induce competitive or cooperative orientation on the part of members of one group toward those of another group. Such an instructional manipulation was used in an experiment by Rabbie, Benoist, Oosterbaan, and Visser (1974) in which three-person groups were instructed to role play a team of union negotiators preparing for a meeting with a management team. After a 10-minute discussion period within the union group, subjects were asked to make ratings of the atmosphere in their own group and of their expectations regarding interactions with the management group. No significant differences in ratings of in-group cohesion or satisfaction were obtained between subjects in the competitive and cooperative orientation conditions, but members of competitive groups did report anticipating greater hostility toward the out-group than did members of groups in the cooperative condition.

Other methods of varying cooperation–competition involve direct manipulation of the structure of the intergroup task. One experiment reported by Kahn and Ryen (1972) used a simulated game setting in which three-person teams anticipated either cooperative or competitive interaction with another team. Before any actual interaction, subjects made ratings of their own team members and of out-group members on 11 evaluative semantic differential scales. A significant difference in ratings in favor of in-group members was obtained from subjects in the cooperative condition, but the size of this difference was significantly greater for subjects in the competitive condition. Such enhancement of in-group bias as a function of intergroup competition has not, however, proved reliable across research studies. Doise et al. (1972) divided subjects into two groups based, supposedly, on preference for photographs, and then led subjects in the experimental groups to anticipate a Tajfel-type money allocation task involving members of both groups. Instructions for allocation were varied to emphasize competitive own-gain maximization (outcomes to be distributed differentially between the groups) or joint-gain maximization (total outcomes to be divided equally between the two groups). Before the allocation task began, subjects evaluated in-group and out-group members on 19 trait scales. Mean ratings from subjects in both the cooperative and competitive conditions showed an in-group bias significantly greater than that obtained from control groups (who anticipated no future task), but the bias for competitive teams was not significantly different from that for cooperative teams (even though behavior afterwards, in the allocation task itself, did differ in a direction consistent with instructions).

One possible explanation of the difference in findings obtained by Kahn and Ryen and by Doise et al. is that the salience of the cooperation–competition manipulation may be highly variable when its impact is assessed prior to actual intergroup interaction. Brewer and Silver (1978) obtained trait ratings of in-group and out-group members from some subjects before they completed an allocation task and from other subjects after the allocations had been completed. Instructions for the allocation task were varied to generate a cooperative intergroup reward structure (achievement determined by adding each in-group member's points to an out-group mem-

ber's points), a competitive reward structure (achievement determined by the difference between points allocated to the in-group member and those allocated to the out-group member), or a reward structure based on total points allocated to the in-group member, regardless of out-group gains. As in the Doise et al. study, performance on the allocation task was significantly affected by these different instruction conditions. Subjects in both the independent and the competitive intergroup conditions predominantly made choices that maximized relative gain in favor of the in-group member, but subjects working under cooperative instructions made fewer relative-gain choices and more choices that maximized joint gain or equality between in-group and out-group member outcomes. However, trait ratings were significantly biased in favor of own-group members by subjects in all conditions, regardless of intergroup reward structure or of whether ratings were obtained before or after the behavioral measure.

Contrary to the Brewer and Silver (1978) findings, Worchel, Andreoli, and Folger (1977) found that intergroup competition significantly increased differential attraction between in-group and out-group in comparison with cooperative or independent intergroup settings. In the first phase of the Worchel et al. experiment, subjects were divided arbitrarily into two groups of four to six persons each. Members of each group were to work together on a joint product that would later be evaluated either in competition with, independently of, or in combination with the product of the other group. After an initial period of interaction, subjects were asked to rate their liking for each of the members of their own and the other group. Only small differences between conditions were obtained for mean attraction ratings of in-group members, but liking for out-group members was significantly higher in the cooperative setting than in the independent setting, and out-group attraction in competitive groups was significantly lower than for either cooperation or independence. On the other hand, Ryen and Kahn (1975) found that competitive interaction with an out-group increased in-group bias, over that obtained in cooperative conditions, by increasing evaluative ratings of in-group members but having no significant effect on out-group ratings.

Since competition is sometimes found to enhance in-group bias effects and sometimes found to have no additional impact,[2] it may be that intergroup competition does not affect intergroup attitudes directly, but only when confounded with other aspects of group differentiation. In other words, the presence of explicit competition may serve to clarify the distinction between in-group and out-group under conditions in which the differentiation would otherwise be ambiguous. The role of intergroup competition in clarifying in-group boundaries can be illustrated with an experiment by Goldman, Stockbauer, and McAuliffe (1977) in which effects of cooperation and competition were compared for both intergroup and intragroup reward structure. In their experiment, two-person teams interacted on a joint task in which achievement outcomes *within* teams were either cooperatively or competitively interdependent, while performance *between* groups was assessed either jointly (cooperatively) or competitively. Evaluative ratings of own-team members were significantly higher under conditions of intragroup cooperation than under intragroup competition, regardless of intergroup reward structure. However, the effects of intragroup competition on task performance were significantly less in the presence of intergroup competition than in the presence of intergroup cooperation. It is very likely that in the latter condition there was no perceptual differentiation between the second member of one's own team and the members of the other team. Only in the presence of a negative correlation between a subject's own final outcomes and those of the other team could such a differentiation be made, which in turn moderated the effects of the competitive task structure within teams. However, Rabbie and Wilkens (1971) reported that intragroup

---

[2] It should be noted that for those studies reporting no significant differences in bias between competitive and cooperative conditions, it is not a matter of results falling just short of statistical significance but rather that the in-group bias obtained is virtually the same under the two conditions.

status differentiation among members of three-person groups increased under conditions of intergroup competition, as compared with cooperative intergroup settings.

Group Outcomes: Success–Failure

One factor that is inherently confounded with the presence of explicit competitive interdependence between groups is that of differential shared fate; that is, under conditions of a competitive reward structure, members of a group share (or anticipate sharing) a common outcome that is distinct from the outcome shared by members of the other group. Such a co-occurrence of group boundaries and common fate is one of the criteria for perceived "entitivity" of social groupings discussed by Campbell (1958). The importance of shared outcomes as a determinant of in-group bias was empirically verified by Rabbie and Horwitz (1969). In that study, arbitrary classification of subjects into two groups labeled *blue* and *green* alone produced no significant in-group bias. However, when the experimenter introduced a chance allocation rule whereby one group won a prize and the other did not, subjects showed a significant bias in evaluative trait ratings (made after the award had been announced) in favor of their own group, regardless of whether their group had won or lost or of what allocation rule had been applied.

Most of the studies of shared fate as a determinant of in-group bias have focused on the effect of group achievement—success versus failure—in a competitive setting. The early management studies by Blake and Mouton (1961) and by Bass and Dunteman (1963) included ratings taken at the end of the intergroup competition phase, after the winning and losing teams had been announced. In both cases, the self-ratings of the winning groups remained significantly inflated (as they were during competition), but the losing groups' self-ratings dropped, at least temporarily. Similarly, Wilson and Miller (1961) found that when win–loss outcomes were experimentally manipulated, evaluative ratings of teammates and out-group members were affected. In comparison with ratings made prior to competition, subjects on winning teams showed a significant increase in bias in favor of their own team members, whereas subjects on losing teams showed a smaller difference in ratings of in-group and out-group members in favor of the winning out-group. Ryen and Kahn (1975) also found that winning under competitive conditions significantly enhanced in-group bias in evaluative trait ratings but that feedback indicating one's own group had lost reduced perceived in-group–out-group differences to nonsignificance.

One experiment reported by Kahn and Ryen (1972) extended the range of win–loss outcomes studied by having groups of subjects engage in a series of simulated football plays and then giving each group feedback information that they had won either 100%, 50%, or 0% of the plays in comparison with another team. After this feedback, subjects made ratings of in-group and out-group team members on 11 evaluative scales. Mean in-group ratings increased (and, to a lesser extent, out-group ratings decreased) as a function of the percentage of in-group success. The resulting differences between mean ratings of in-group and out-group were not significantly different from zero for groups with no wins (mean in-group–out-group difference $= -1.5$), were significantly biased in favor of one's own group for those with 50% wins (mean difference $= 8.3$), and were significantly more biased for those with 100% success (mean difference $= 14.5$).

In the preceding experiment, in-group bias occurred even when outcomes for the in-group were the same as those obtained by the out-group (50% wins), as long as the in-group attained some degree of success. In a second experiment, Kahn and Ryen (1972) tested whether differentiation between in-group and out-group outcomes was an important factor in in-group bias when competitive interdependence between groups was removed. Groups of three subjects worked independently on selected IQ test items, and then each group was given feedback indicating whether their performance resulted in a high proportion of successes or a low proportion of successes (high failure) and also whether

the other group's performance was high or low, with in-group and out-group results manipulated independently. After this feedback was provided, evaluative ratings were obtained of in-group and out-group members. Under these noncompetitive conditions, subjects in all conditions showed a bias in favor of their own group, but the degree of bias was significantly enhanced only when in-group success was combined with out-group failure.

Across these studies involving group performance outcomes there appears to be a consistent tendency for subjects to exaggerate the difference between in-group and out-group qualities when the in-group does well in comparison with the other group but to reduce the perceived difference when in-group and out-group performed the same or when the in-group does more poorly. Such a pattern serves to maximize favorable comparisons and to minimize unfavorable ones and may be typical of responses to single, or one-time, intergroup comparisons. Responses to success and failure may change, however, if interactions are extended in time and further comparisons between in-group and out-group are anticipated in the future. Worchel, Lind, and Kaufman (1975) found that anticipation of further competition interacted with outcome feedback in determining relative evaluation of in-group and out-group products. Members of winning groups overevaluated their group product less when they expected competition between the groups to continue than when they expected it to discontinue, whereas members of losing groups devaluated their group product more under discontinuing than under continuing conditions. Worchel et al. interpreted these results in the context of ongoing competition to avoid "complacency" on the part of winning groups and to avoid "giving up" on the part of losing groups.

Continued failure or deprivation of the in-group relative to a particular out-group across a long period of time may lead to compensatory overevaluation in favor of the in-group wherever possible (LeVine & Campbell, 1972). Branthwaite and Jones (1975) looked at the effect of long-standing status differentials between ethnic groups on allocations in the Tajfel choice task. When subjects were divided into groups according to ethnic identity (Welsh–English), members of the minority group made more choices that maximized the difference between in-group and out-group member outcomes than did members of the majority group (who tended to make more choices dictated by equality or joint-gain maximization). Similar findings were obtained by Gerard and Hoyt (1974) with experimentally created groups and a different measure of bias. Subjects in their study were classified as members of a group of 2, 5, or 8 subjects, out of a total of 10 subjects participating in a session. Each subject was then asked to make evaluative ratings of essays supposedly written by two other participants in the experiment—one identified by an identification number of someone in the subject's own group and one identified by an identification number from the out-group. Ratings of the content of the essays produced no in-group–out-group differentiation, but evaluations of the writers resulted in some differences. Subjects classified into groups of five and eight showed no significant bias (in fact, there was some tendency in favor of the out-group member), whereas subjects in the minority group of two showed a significant positive bias in favor of their in-group member.

Results from both of these studies suggest that minority group status makes in-group membership more salient than does membership in a majority group. A similar heightening of awareness of group identity may occur for groups exposed to repeated failure or loss, particularly when membership in such a group is unalterable. Whether repeated failure ultimately generates greater in-group–out-group differentiation than does repeated success has yet to be experimentally demonstrated. However, in a survey of intergroup perceptions among ethnic groups in East Africa, Brewer and Campbell (1976) found those groups rated lowest on the socioeconomic status index to be higher in ethnocentric self-regard than those groups with the highest socioeconomic status ratings. This effect may also be related to repeated findings

of "reverse discrimination" on the part of members of high-status majority groups in dealings with individual members of minority groups (Dutton, 1976).

Intergroup Similarity

Although it has been established that evaluative bias occurs only in the presence of some meaningful distinction between groups (Rabbie & Horwitz, 1969), the minimal differentiation required allows room for considerable variation in implied or explicit similarity between members of the in-group and out-group. A number of studies have examined the effect on in-group bias of variations in degree of similarity among in-group members, or of dissimilarity between in-group and out-group, on such dimensions as cultural, personality, or attitudinal characteristics.

Wilson and Kayatani (1968) divided subjects into two-person teams, with each team composed of members of the same racial group (Japanese or Caucasian). Each team then played a modified Prisoner's Dilemma Game with another team of the same or different race. The game choice results were uniform across both types of out-groups—choices made in the intergroup setting averaged only 43% cooperative, whereas choices made within each group averaged 84% cooperative. Similarly, postgame evaluative trait ratings showed a significant in-group bias regardless of whether the out-group was of the same or different race.

A more recent study by Dion (1973) also looked at the effect of similarity on intergroup versus intragroup Prisoner's Dilemma Game behavior. The experimental manipulation in this study, however, varied intragroup rather than intergroup similarity. One half of the dyads in the experiment were told that the members had closely matched personality profiles, whereas the remaining pairs were told they had discrepant profiles. All teams then played a Prisoner's Dilemma Game (with two experimental confederates serving as the out-group team) and also rated both in-group and out-group members on 16 evaluative traits. Both high- and low-similar dyads exhibited the same intergroup game behavior (averaging 30% cooperative choices), but the high-similar pairs exhibited significantly more in-group cooperation (59%) than did the low-similar pairs (36%). The same pattern of results was obtained for the evaluative ratings: Out-group ratings were essentially the same for all groups, while in-group ratings were significantly higher for members of the high-similar dyads.

Billig and Tajfel (1973) compared intergroup differentiation based on explicit similarity with categorization based on no similarity principle. In their experiment, intergroup similarity and categorization were manipulated independently. Similarity was varied by dividing half the groups according to supposed preferences in painting styles (Klee vs. Kandinsky) and by dividing the remaining groups randomly into groups labeled *X* or *W*. Categorization was varied by including group label as part of subject identification during the allocation task for some subjects and omitting group labels for others. Results from the allocation task showed significant in-group favoritism in the categorization conditions and no significant favoritism in the noncategorization conditions, regardless of similarity. Brewer and Silver (1978) also found significant in-group bias on both allocation-task decisions and evaluative ratings regardless of whether groups had been formed on the basis of distinct preferences or had been formed on the basis of a random split after being explicitly told that all subjects were similar on the preference task.

The similarity manipulation in the Billig and Tajfel and the Brewer and Silver studies involved both intragroup similarity and intergroup dissimilarity. In an experiment by Allen and Wilder (1975) these two facets were varied independently in a 2×2 design. With painting style preference as the ostensible basis of categorization into groups, subjects were provided with further information indicating the percentage (high or low) of responses to an attitude questionnaire that were similar to their own responses for other members of their own group and for members of the other group. Subjects then

made choices on the Tajfel allocation task on behalf of an in-group member and an out-group member. Subjects in all experimental conditions showed some degree of in-group favoritism in allocation decisions. High in-group similarity produced significantly more bias than did in-group dissimilarity, but similarity–dissimilarity of the out-group had no effect on degree of in-group bias.

Results from all of these studies are consistent in indicating that explicit dissimilarity within the in-group reduces in-group bias but that information on similarity between the subject and out-group members makes no difference. However, it may be that perceived similarity within the in-group and perceived dissimilarity from the out-group are highly interdependent, as suggested by the results of an experiment by Hensley and Duval (1976). In this study, information on the opinions held by 10 subjects in a discussion group was presented graphically in such a way that each subject's own opinion was depicted within a cluster of seven other subjects' opinions, with the distance between the subject's opinion and these seven held constant. The positioning of the opinions associated with the remaining 2 subjects was varied across five levels of distance from this majority cluster. Following this presentation, each subject made ratings of the other 9 subjects in the session on perceived similarity to self and on liking. The results for perceived similarity ratings revealed an assimilation–contrast effect: The greater the distance between the minority (out-group) and the majority (in-group), the greater the perceived similarity within the subject's own group. A parallel effect was obtained on the ratings of liking for members of the majority and minority groups.

Salience of Categorization

Since the grouping of subjects into majority and minority clusters in the Hensley and Duval study was not explicitly labeled, it is likely that the effect of increasing the visual distance between the two clusters was to increase the probability that the subject would perceive a boundary between the two groups. In fact, in the three conditions in which the distance between clusters was great enough to insure the perception of distinct groupings, the ratings of perceived similarity and of liking for in-group as opposed to out-group members were essentially the same, the only significant differences occurring between these three conditions and the two conditions involving lesser distances. Thus, the effect attributed to out-group dissimilarity may have been due to the differential salience of the in-group–out-group distinction. Other research in which the salience of categorization has been manipulated either directly (e.g., Billig & Tajfel, 1973) or indirectly (e.g., Gerard & Hoyt, 1974) confirms the importance of this factor in eliciting in-group bias.

Results of several studies indicate that the same differences among individuals may or may not lead to bias depending on whether a basis for grouping has been made salient. For instance, in a study by Stephenson, Skinner, and Brotherton (1976), secondary school students were assessed on their attitudes toward raising the age for compulsory schooling. Experimental sessions were composed of four students in favor of and four against raising the age. At the beginning of the session subjects were given information about the distribution of attitudes among the eight participants and then were asked to rate each of the participants on five evaluative trait scales. Ratings were made both before and after subjects were divided into four-person groups (based on initial attitudes) for participation in an intergroup negotiation task. Prior to the division into labeled groups, ratings showed no in-group bias, but following the group task, ratings changed significantly in favor of the in-group.

Turner (1975) also reported a complex interaction between participation in an intergroup task and in-group favoritism. Subjects in his study were divided into two groups and then made two sets of choices on a Tajfel allocation task—once making choices on behalf of two other subjects (one of whom was an in-group member and one an out-group member) and once making choices on behalf

of self and one other subject (who was either an in-group member or an out-group member). For subjects who made self–other choices first, favoritism toward self was moderately high, regardless of whether the other was an in-group member or an out-group member. However, for subjects who made in-group–out-group member choices before making self–other choices, self-favoritism was significantly higher when the other was an out-group member than when the other was an in-group member. Thus, prior participation in a task that made the intergroup distinction salient enhanced the differentiation between self and out-group member, but reduced differentiation between self and in-group member.

The mere presence of more than one member of a distinct social group apparently increases the salience of grouping and associated biases. Dustin and Davis (1970) observed the effects of competition between two groups of three subjects when the competitive interaction took place on an individual (1:1) basis or on a group (3:3) basis. Following group competition, product ratings were significantly biased in favor of subjects' in-group output, but no own-group bias was obtained for product ratings from subjects whose groups interacted on an individual competition basis. Similar effects have been obtained for biases associated with nonexperimental social groups. Doise and Sinclair (1973) studied the effect of reference group salience on accentuation of stereotypes associated with *collegians* (male secondary school students) and *apprentis* (vocational trainees). Members of both groups were brought together in either a 1:1 or a 2:2 encounter and, following a short discussion period, were asked to make trait ratings of the respective groups. In the 2:2 condition collegians gave ratings significantly more biased in favor of their own group than they did in the 1:1 condition, whereas apprentis showed less derogation of their own group relative to the higher status out-group in the 2:2 than in the 1:1 condition. Similar effects of the presence of multiple members of both groups have been obtained for accentuation of stereotypes based on sex (McKillip, Dimiceli, & Luebke, 1977) and on ethnic identity (Dion & Earn, 1975).

Summary

The interpretation of results from all of the experimental studies reviewed in this section (entitled Sources of Variation in Bias) has been consistent with the following general conclusion: Any of the situational factors found to be associated with enhancement of in-group bias can be subsumed under the effect of the salience of the distinction between in-group and out-group. Factors such as interdependence, intergroup similarity, and shared fate all affect the probability that a respondent will be aware of a relevant basis for categorization into groups, which in turn determines the amount of in-group bias that is evidenced. Once a particular categorization has become salient, however, the degree of bias obtained is fairly constant despite further variations in out-group similarity (e.g., Allen & Wilder, 1975) or in opportunity for cooperative interaction (e.g., Brewer & Silver, 1978; Worchel et al., 1977).

Locus of Bias: Which Dimensions?

Though the argument has been made that in-group bias is related in an all-or-nothing manner to category salience, the bias associated with any particular basis for categorization into in-group and out-group may not be constant across all response dimensions. There are a number of sources of evidence for specificity of effects, or "selective bias" (Wilson, Chun, & Kayatani, 1965). A series of studies by Wilson and his associates (e.g., Wilson et al., 1965; Wilson & Kayatani, 1968) indicate that following intergroup competition within a Prisoner's Dilemma Game format evaluative bias is most pronounced on game-relevant motive traits (e.g., cooperative, fair, and kind), whereas in-group bias is less pronounced on sociometric (e.g., likeable) or ability traits (e.g., capable and intelligent) and least evident on general personality dispositions (e.g., neurotic and

anxious). Dion (1973) also found that in-group bias after participation in an intergroup Prisoner's Dilemma Game was greatest on the dimension of trust, and Brewer and Silver (1978) obtained the most bias on ratings of trustworthiness, friendliness, and cooperativeness, even after respondents had engaged in a cooperative intergroup allocation task. The latter study also found a nonsignificant correlation ($r = .14$) between in-group favoritism on the allocation task and in-group bias on evaluative trait ratings. Similarly, Ryen and Kahn (1975) obtained no significant correlation between evaluative in-group bias and intergroup distancing, as evidenced in seating behavior, and Worchel et al. (1975) reported a low correlation between liking for the in-group and relative evaluation of in-group versus out-group products. Going outside of the laboratory, Brewer and Campbell (1976) found in a large-scale survey of intergroup attitudes that the psychological distance reported between a respondent's in-group and a particular out-group varied depending on whether the response measure dealt with affective relations (e.g., social distance), evaluation, or respect.

The finding that bias depends on some interaction between the categorization variable and the response dimension on which bias is assessed is consistent with a cognitive interpretation of intergroup bias (Tajfel, 1959; 1969). The comparison with general theories of cognitive processing is best illustrated by Tversky's (1977) feature-matching model of similarity judgments. In Tversky's model, the perceived similarity between two objects is a function of some linear combination of their common and distinctive features; but the weight assigned to any particular feature or set of features may vary depending on the context or the nature of the judgment task. As a result, the same two objects may be judged to be highly similar within one frame of reference and highly distinct within another. The determinants suggested by Tversky for this lability of perceived similarity are relevant to the judgment of objects external to the respondent. It may be that when identification with oneself is a salient feature of one of the objects to be judged, motivational factors enter into the selection of features to be attended to (cf. Christian, Gadfield, Giles, & Taylor, 1976).

The interdependence of perceptual and motivational factors is highlighted by some interesting parallels between the research literature on perceptual accentuation in social judgment (Eiser & Stroebe, 1972) and on in-group bias effects (Turner, 1975). In the judgment literature, *enhancement of contrast* occurs when the judged distance between stimuli that are members of different classes is exaggerated. The occurrence of this accentuation effect depends on the presence of at least some minimal correlation between the classification variable and variation among the stimuli on the property being judged (Campbell, 1956; Tajfel, 1959; Tajfel & Wilkes, 1963). However, when the stimuli are social objects, toward which the judge has differential orientations, a second condition has been found to be necessary for enhancement of contrast, namely, that the judge's own position be located on what the rater perceives to be the positive side of the dimension of judgment (Eiser, 1975; Eiser & Mower-White, 1974).

Analogous to the conditions associated with the enhancement of contrast effect, Turner's (1975) social comparison theory of in-group favoritism specifies two preconditions: (a) salience of some basis for distinction between in-group and out-group and (b) availability of "differentially valued actions relevant to the categorization" (p. 12). The presence of these conditions generates intergroup *social competition,* the aim of which is to take advantage of opportunities to maximize the relative advantage of the in-group over the out-group. In effect, then, in-group bias results from a motivated search to represent the differences between groups along dimensions that favor the in-group. If outcomes favoring the in-group are not available, the distinction between them will be minimized rather than accentuated.

The presence of motivational influences can lead to important asymmetries in the ways in which the members of two social groups perceive the differences between them, such as those obtained for groups differing

in socioeconomic status (e.g., Branthwaite & Jones, 1975; Brewer & Campbell, 1976). Members of Group A may perceive a major difference between themselves and Group B along dimension *X*, whereas members of Group B may focus on the common features of A and B relevant to *X* and emphasize the distinctive features relevant to dimension *Y*. (Imagine, e.g., members of a winning team following a football contest and highlighting the differences between the teams in agility and skill, while members of the losing team regard ability differences as marginal, but emphasize differences between the teams in "how the game was played" with respect to fair play and sportsmanship.) Even differences on a single dimension can be represented in alternative ways that favor one group or the other (Campbell, 1967; Peabody, 1967; Vassiliou, Triandis, Vassiliou, & McGuire, 1972). For example, an objective difference between the customs of two groups with regard to the sharing of household items may be represented by one group as a distinction between generosity and selfishness, but may be defined by the other group in terms of responsibility–irresponsibility. Such differences can introduce considerable variation in assessments of in-group bias.

Although not all differences can be represented in a manner congruent with positive self-image, some characteristics of groups lend themselves to universal bias. Across experimental and field studies of the content of intergroup perceptions, the dimensions on which evaluative bias in favor of in-groups occurs most reliably are those associated with trustworthiness, honesty, or loyalty. All these are traits related to normative expectations that apply to intragroup—as opposed to intergroup—behavior. To the extent that norms prescribing preferential treatment for members of one's own group are characteristic of in-group formation, they generate a set of reciprocal stereotypes (Campbell, 1967) that any two groups might have of each other and with which each could legitimately place the in-group on the positive side of the scale (e.g., "we are loyal; they are clannish"; "we are honest and peaceful among ourselves; they are hostile and treacherous toward outsiders"). This reciprocal contrast is basic to the "mirror-image" phenomenon in international perception, as portrayed by Bronfenbrenner (1961).

Locus of Bias: In-Group or Out-Group?

The extensive literature on group cohesiveness indicates that factors such as similarity among group members (e.g., Anderson, 1975) and shared success (e.g., Blanchard, Adelman, & Cook, 1975) enhance attraction toward one's own group in the absence of comparison with any other groups. Since in-group bias research focuses on favoritism toward the in-group *relative* to an out-group, it is often ambiguous whether the comparison rests on enhancement of the in-group, devaluation of the out-group, or both. In many studies, particularly those dealing with evaluative biases, results were reported only in the form of net ratings or difference scores (e.g., Doise & Sinclair, 1973; Dustin & Davis, 1970; Ferguson & Kelley, 1964; Gerard & Hoyt, 1974; McKillip et al., 1977), thereby losing information as to whether variations in bias were a function of increases in in-group ratings or decreases in out-group ratings.

Among those studies that did report both in-group and out-group ratings separately, results are mixed as to the location of bias. Some studies that compared intergroup cooperation and competition reported no change in in-group attraction, but reported a decrease in out-group ratings under competition conditions (Rabbie et al., 1974; Worchel et al., 1977). Other research indicates that variations in degree of bias are a function of both increased in-group and decreased out-group ratings (Hensley & Duval, 1976; Kahn & Ryen, 1972; Wilson et al., 1965). The majority of studies, however, indicate that increases in bias are associated with enhanced in-group evaluation, whereas out-group ratings remain relatively constant (Dion, 1973; Rabbie & Horwitz, 1969; Rabbie & Wilkens, 1971; Ryen & Kahn, 1975; Stephenson et al., 1976; Wilson & Miller, 1961; Worchel et al., 1975). The results in general, then, are consistent with the conclu-

sion that in-group bias rests on the perception that one's own group is better, although the out-group is not necessarily depreciated.

The above conclusion suggests that the effect of in-group–out-group categorization is one of differentiating the in-group from the out-group rather than of differentiating the out-group from the in-group, as the process is usually conceived. This means that the baseline should be conceptualized as a state in which the self is perceived as distinct from an undifferentiated group of others. The introduction of an in-group–out-group boundary is then associated with a realignment of perceptions wherein members of the in-group are perceived to be less differentiated from the self, while the distance between the self and out-group members remains unchanged. This conceptualization of the differentiation process is borne out by studies that modified the Prisoner's Dilemma Game for group play (e.g., Dion, 1973; Wilson & Kayatani, 1968). In terms of the high percentage of competitive choices, intergroup behavior in these games parallels closely the game behavior of individual players. It is the increased proportion of cooperative choices exhibited in intragroup decisions that deviates from typical interindividual play.

Reconceptualizing the process of intergroup differentiation tends to shift the focus of attention from the negative implications of out-group perceptions to the positive consequences of in-group formation. The critical role of in-group identity in the extension of interpersonal trust has already been alluded to. Another consequence of the reduced social distance between self and others that accompanies in-group formation is that outcomes to other group members, or to the group as whole, come to be perceived as one's own. Indeed, there is evidence that feedback regarding total group outcomes can have more impact on the individual than feedback on his or her own performance (e.g., Zander & Armstrong, 1972) and that expected and perceived success is higher at the group level than at the individual level (Janssens & Nuttin, 1976). Satisfaction and identification with group success tend to be high even when the individual's contribution to that success has been minimal (e.g., Kahn & Ryen, 1972) or nil (Cialdini et al., 1976).

The capacity of in-group identification to amplify feedback has important implications for the solution of that class of social problems characterized as *commons dilemmas* (Dawes, McTavish, & Shaklee, 1977; Hardin, 1968) or *social traps* (Platt, 1973). The essence of these problems is a "divergence between what people are individually motivated to do and what they might accomplish together" (Schelling, 1971, p. 68). The most critical social dilemmas derive from behaviors for which rewards outweigh small costs at the *individual* level (e.g., taking an extended shower) but that result in cumulative high costs at the *group* level (e.g., depletion of water supplies). The solution to such dilemmas requires that the collective outcome be real enough to the actor to overcome individualistic motivational dynamics (Messick, 1973; 1974). The reduced differentiation between one's own and other outcomes associated with in-group formation provides one mechanism for increasing the weight given to collective outcomes in individual decision making.

The idea of capitalizing on the social benefits of group identification raises concern about whether the positive consequences of in-group formation depend on the presence of a distinct out-group. To those who hold that the effects of social categorization are the result of intergroup social comparison (Turner, 1975; Tajfel, in press), the existence of an identifiable out-group is essential. Although groups may function in the absence of any other groups, the mere presence of an out-group is sufficient to significantly alter in-group processes (Billig, 1976). On the other hand, if one associates group identification with more general concepts of unit formation (Campbell, 1958; Heider, 1958), awareness of differentiated social groupings may be only one potential mechanism—however important—by which the self is included in a bounded social unit. Perhaps the salience of interdependence or common fate can be enhanced among any given set of individuals without reference to other subsets. If so, the focus of research on in-

group bias should be shifted from intergroup to intragroup contexts.

A Simplex Process Model for Describing Differences Between Cross-Lagged Correlations

Lloyd G. Humphreys and Charles K. Parsons
University of Illinois at Urbana-Champaign

A model that is based on the use of the diagonal method of factoring to describe a simplex process and that explains differences between cross-lagged correlations is presented. When the model is applied to the data of Atkin et al., which showed that Listening tapped most directly the causes of later intellectual development, quite good fits are obtained for both 2- and 4-year lags. The best fit, however, is based on an estimate of the effects of a 3-year lag between changes in the rank order of individual differences on the Listening test and the same changes on the intellectual composite. It is shown that accurate knowledge of reliabilities and specificities of the measures is necessary for the interpretation of cross-lagged differences but that stationarity per se is not an essential assumption.

The first reaction of most behavioral scientists to a discussion of cross-lagged panel correlation methodology is to question the inference of causality from a difference in the size of correlations. It does not matter how large or how statistically significant the difference may be. Discussions of this methodology, such as those by Campbell and Stanley (1963) and by Kenny (1975), have not provided a rationale that is sufficient to satisfy these skeptics. The purpose of this article is to describe a factor model that provides a new and plausible basis for a possible causal inference and to apply it to some published data.

Simplex Correlation Matrices

Since the cross-lagged methodology is used in the expectation that there will be change in the rank order of individual differences in the functions measured with the passage of time, one should also expect that the intercorrelations of each of the two or more measures over multiple occasions will show the simplex pattern (Guttman, 1955; Humphreys, 1960; Rozelle & Campbell, 1969). Guttman used the simplex matrix originally to describe the intercorrelations of several measures on a single measurement occasion when the several measures seemingly varied only in their degree of complexity. Humphreys extended the applicability of the simplex pattern to learning and maturational data in which one measure was obtained on repeated occasions. Rozelle and Campbell discussed the simplex matrix with respect to time series generally. Both Guttman and Humphreys argued against the use of multiple or common factor analysis as appropriate for such data.

In place of common factor analysis, Guttman recommended the use of diagonal factoring, which produces the same number of factors as there are variables in the correlation matrix. If the measures are ordered in increasing order of complexity, the first factor is based on the correlations that involve the simplest measure, and the nth is based on the residual correlations that involve the most complex measure. For learning data, if one assumes accretion of responses, the first factor is based on the correlations that involve the

Table 1
A Simplex Matrix of Intercorrelations and Its Diagonal Factoring

Occasion	1	2	3	4
		Occasion		
1	1.000	.960	.922	.885
2	.960	1.000	.960	.922
3	.922	.960	1.000	.960
4	.885	.922	.960	1.000
		Factor		
1	1.000	.000	.000	.000
2	.960	.280	.000	.000
3	.922	.268	.280	.000
4	.885	.259	.268	.280

first trial; if learning seemingly involves the dropping out of unnecessary responses, the first factor is based on the correlations of the *n*th trial with all of the others. In both cases factors are extracted from successive tables of residuals in the serial order of the learning trials, either forward or backward in time. Similar reasoning holds for developmental data.

An Arbitrary Example

The applicability of diagonal factors to changes over time can be illustrated by an arbitrary example. Table 1 presents a 4×4 matrix of intercorrelations of the hypothetical variable X, which is measured with perfect reliability. Also appearing in this table are the diagonal factors. The first occasion is used to define Factor 1, followed in order by the second, third, and fourth occasions defining Factors 2, 3, and 4.

Although the diagonal method can be applied to any matrix of intercorrelations, it has special properties when used for the simplex. For one thing, the ordering of the variables determines the order in which factors must be extracted if one wishes to portray the special characteristics of the simplex matrix. Secondly, whether factoring starts with the first or the *n*th variable, the factor matrix has one triangle of zero loadings and a second triangle of positive nonzero loadings. The factor matrix directly reflects causes of change. Causes operative before the first measurement occasion, extending backward in time over the history of the organism, are aggregated in the first factor, with the major effect on the first occasion but with effects on all subsequent occasions as well. As new causes of change enter the picture between measurement occasions, the effects occur only on subsequent occasions. New causes appear between each pair of occasions.

The intercorrelations over multiple occasions of each of the two or more measures being studied can be factored by the same methodology, but it is not essential to the accurate description of the intercorrelations that the first factor be defined by the first occasion for each measure. Several different diagonal factorings of the intercorrelations presented in Table 1 are shown in Table 2 for the hypothetical variable Y, which is a variable possibly influenced by X. Although an infinite number of possible rotations are possible mathematically, the four illustrated in Tables 1 and 2 are the appropriate ones for present purposes.

Note that the factoring for variable X could also be extended backward in time. Occasions -1, -2, and -3 would produce columns of factor loadings parallel to those of Factors 3, 2, and 1, respectively, in the Lag 3 factoring of variable Y. Diagonal factoring of X and Y can go on indefinitely both forward and backward in time. For purposes of describing the intercorrelations of each independently of the other, the choice of the occasion on which one decides to start factoring is highly arbitrary.

For purposes of describing a cross-lagged difference, however, choice of occasion is not arbitrary. Factor 1 in X, extracted at Time 1, is identified with a factor in Y, depending on the lag hypothesized, at Time 2, 3, or 4. Depending on this decision, the factor matrix in Table 2 that represents the appropriate lag is selected to represent variable Y. This matrix is then modified by deleting one, two, or three columns from the left-hand side, depending of course on the time lag hypothesized, and adding the same number of columns of zeros on the right. The factor matrix of X is now postmultiplied by the transpose of the

Table 2
Three Alternative Factorings of the Intercorrelations of Table 1

	Factors for Lag 1				Factors for Lag 2				Factors for Lag 3			
Occasion	1	2	3	4	1	2	3	4	1	2	3	4
1	.280	.960	.000	.000	.280	.268	.922	.000	.280	.268	.259	.885
2	.000	1.000	.000	.000	.000	.280	.960	.000	.000	.280	.268	.922
3	.000	.960	.280	.000	.000	.000	1.000	.000	.000	.000	.280	.960
4	.000	.922	.268	.280	.000	.000	.960	.280	.000	.000	.000	1.000

modified Y factor matrix to produce the cross-correlations between the two variables. The discard of factors in Y that preceded the factor identified with Factor 1 in X prior to the matrix multiplication is justified on the basis that they were determined by factors in X that preceded the present Factor 1.

This model can readily be related to the common interpretations of cross-lagged differences. These interpretations have been arranged in order from the one that is closest to the observations and therefore basic to all of the others to the one that clearly requires additional research to establish. The first interpretation, also, serves as the basis for equating an earlier factor in X with a later factor in Y. The interpretations are as follows:

1. Individual differences in X anticipate in time individual differences in Y.
2. Variable X at Time 1 taps the causes for changes in Y that appear subsequent to Time 1.
3. The predominant causal sequence is from X to Y rather than from Y to X.
4. Changes in X cause changes in Y.

A more formal treatment of the argument up to this point follows. Let X be the hypothesized antecedent variable and Y the consequent variable. $\mathbf{F}_x$ is a diagonal factor matrix determined from $\mathbf{R}_x$, and $\mathbf{F}_y$ is a diagonal factor matrix determined from $\mathbf{R}_y$.

$$\mathbf{R}_x = \mathbf{F}_x\mathbf{F}'_x. \tag{1a}$$

$$\mathbf{R}_y = \mathbf{F}_y\mathbf{F}'_y. \tag{1b}$$

Now let $\mathbf{F}_{y_1}, \mathbf{F}_{y_2}, \cdots, \mathbf{F}_{y_n}$ represent factor matrices in which the first column represents the first diagonal factor extracted whether that factor represents Time 1, 2, or n. The $\mathbf{F}_{y_1}$ matrix contains no column of zeros on the right, but all others contain one or more columns of zeros up to $n - 1$ such columns for $\mathbf{F}_{y_n}$.

$\mathbf{R}_{xy} = \mathbf{F}_x\mathbf{F}'_{y_1}$ with time lag of zero between X and Y (no cross-lagged difference observed). (2a)

$\mathbf{R}_{xy} = \mathbf{F}_x\mathbf{F}'_{y_2}$ with time lag of one between X and Y. (2b)

$\mathbf{R}_{xy} = \mathbf{F}_x\mathbf{F}'_{y_n}$ with time lag of $n - 1$ between X and Y. (2c)

Three different sets of possible cross-correlations are shown in Table 3, based upon lags of one, two, and three occasions, respectively. When the lag is one interval, it is seen that the maximum cross-lagged difference occurs at

Table 3
Cross-Correlations Between X *and* Y *for Three Lags*

	Y for Lag 1				*Y* for Lag 2				*Y* for Lag 3			
X	1	2	3	4	1	2	3	4	1	2	3	4
1	.960	1.000	.960	.922	.922	.960	1.000	.960	.885	.922	.960	1.000
2	.922	.960	1.000	.960	.885	.922	.960	1.000	.850	.885	.922	.960
3	.885	.922	.960	1.000	.850	.885	.922	.960	.816	.850	.885	.922
4	.850	.885	.922	.960	.816	.850	.885	.922	.783	.816	.850	.885

that interval; but there is little drop in size at intervals of two or three. When the lag is more than one interval, the maximum cross-lagged difference occurs at the appropriate interval. With zero lag, there are no cross-lagged differences.[1]

Required Additions to the Model

The preceding discussion contains the heart of the model, but it is deficient in three particulars. The matrix multiplication required for Table 3 assumes a one-to-one correspondence between factors in X and Y when the appropriate time lag is selected. This is unrealistic. The most obvious lack is failure to allow for measurement error. When the application is to fallible data, one must substitute reliabilities for the unities in the principal diagonal of the correlation matrix before factoring. Diagonal factoring with reliabilities in the principal diagonal of the R matrix can produce negative residuals that in turn produce negative factor loadings. If the R matrix can be considered to represent a simplex process with little error, residuals from diagonal factoring that would be zero if unities had been used will be very small positive or negative values that can be disregarded.

This means that the matrix multiplications in Equations 1a and 1b still hold, with the exception that the R matrix is defined with reliability estimates rather than with unities in the principal diagonal. This also means that knowledge of reliabilities is an essential requirement in analyzing cross-lagged differences by means of the present model. In this respect the model does not differ from other methods of analysis (see especially, Kenny, 1975).

A second problem is that practically all measures used in the behavioral sciences contain unique nonerror (specific) variance in addition to common factor and error variance. It is logically impossible for the specific variance in X to be related in any way, causally or otherwise, to individual differences in Y. One way or another it is necessary to obtain an estimate of the specificity of both X and Y relative to each other. When circumstances are appropriate, specifics can be estimated by common factor analysis or by multiple regression analysis. At times psychometric analysis suffices. Again, as with measurement error, knowledge of specifics is an essential requirement in analyzing cross-lagged differences. Either reliability differences or specificity differences from one occasion to another can produce completely spurious cross-lagged differences. In Kenny's discussion of a correction for reliability–specificity differences, the two are legitimately merged in the concept of uniqueness.

The presence of specificity does lead to a change in Equations 2a, 2b, and 2c. Two new matrices are required. The first, $\mathbf{H}_x$, is a diagonal matrix consisting of $h_1, h_2, \ldots, h_n$. These values are determined from the proportions of common (h^2) and specific (s^2) variance in the true score variance of X at each time period. The matrix $\mathbf{H}_y$ is defined in parallel fashion. In contrast to $\mathbf{F}_y$, which is modified in accordance with the hypothesized lag, $\mathbf{H}_y$ is independent of lag, that is, $\mathbf{H}_y$ characterizes the measures. If $\mathbf{F}_x$ and $\mathbf{F}_y$ now represent the factors extracted from fallible measures, Equations 2a, 2b, and 2c are rewritten as follows:

$$\mathbf{R}_{xy} = (\mathbf{H}_x\mathbf{F}_x)(\mathbf{F}'_{y_1}\mathbf{H}_y). \quad (3a)$$

$$\mathbf{R}_{xy} = (\mathbf{H}_x\mathbf{F}_x)(\mathbf{F}'_{y_2}\mathbf{H}_y). \quad (3b)$$

$$\mathbf{R}_{xy} = (\mathbf{H}_x\mathbf{F}_x)(\mathbf{F}'_{y_n}\mathbf{H}_y). \quad (3c)$$

The third lack in the general model is only a little less ubiquitous than the presence of measurement error and specificity, but is not as important in its contribution to variance or to model fitting. This source of variance is correlated error that inflates the correlations between variables that are measured on a single occasion. This third component, by definition, can affect only the synchronous correlations among measures and cannot produce spurious cross-lagged differences. Knowl-

[1] These relationships are, of course, the effects of the assumption of a correlation of .96 between true scores on adjacent measurement occasions for both X and Y. This level of correlation was selected as a representative figure for ability measures. Its constant size over both variables and occasions represents the assumption of stationarity that is later discarded. A lower correlation or one that varied from one occasion to another or from one variable to another would have rather different effects.

Table 4
Intercorrelations of Listening and the Composite in Four Grades for 1,430 White Boys and Girls

Test and grade	Listening 5	Listening 7	Listening 9	Listening 11	Composite 5	Composite 7	Composite 9	Composite 11
Listening

5						.928	.888	.862
7							.938	.912
9								.930
11								

edge of this source of varance is not, therefore, essential. Absence of this information, however, will prevent one from obtaining a good fit of the synchronous correlations to empirical data.

Aural Comprehension and Intellectual Development

Atkin et al. (1977b) obtained cross-lagged differences that involved a measure of aural comprehension and an intellectual composite of 15 separate cognitive tests. The direction of the differences was that the Listening test predicted the composite more highly than the composite predicted Listening. The differences were also highly significant both statistically and psychologically. Four groups defined by race (black and white) and sex were studied on four occasions, at Grades 5, 7, 9, and 11. Results were highly consistent for the four groups and for the six pairs of occasions, with only one small exception out of 24 comparisons. The size of the difference between the cross-lagged correlations for the four groups in most of the comparisons was between .10 and .20.

In this research the composite that was compared with the Listening test was formed from the following tests: the two tests of School and College Aptitude, the five tests other than Listening from the Sequential Tests of Educational Progress, and the eight narrow information tests that cover heterogeneous areas from the Test of General Information.[2] Similar comparisons for each of the 15 tests in this particular composite with a rotating composite formed in each case from the remaining members of the original set of 16 were also made. Optimum weights obtained from multiple regression and canonical analysis were used to form each composite, but with large *N*s there is little capitalization on chance in the obtained values. No other measure in the set of 16 showed differences that even approached in size or consistency those shown by the Listening test.

To apply the model to these data we decided to combine all correlations that involved white males and females. These two groups contained the larger number of cases (668 males and 762 females). It is also known that the common factor patterns of the 16 tests at each grade level are highly similar for the two white groups (Atkin et al., 1977a). Blacks are not known to differ, but there is more sampling error "noise" in their data. The mean correlations, based on equal weights for the two sexes, are presented in Table 4. When one compares this table with the cross-correlations in Table 3, the asymmetry characteristic of a lag between X and Y is readily apparent.

At present, fitting of the model to the data

[2] These tests are published by the Educational Testing Service (ETS). The data analyzed by Atkin et al. (1977b) were made available by Thomas Hilton and ETS. We owe them thanks for their gracious cooperation.

Table 5
Reliabilities and Specifics for Listening and the Composite in Grades 5, 7, 9, and 11

Statistic	Listening				Composite			
	5	7	9	11	5	7	9	11
Reliability	.743	.817	.753	.693	.937	.981	.957	.947
Specific variance	.106	.108	.084	.066	.000	.000	.000	.000

proceeds one step at a time. The first step requires estimates of reliabilities. In the absence of an experimental design that would make possible test–retest or parallel-forms estimates, it is necessary to assume that the intercorrelations of true scores over the four time periods form simplex matrices. The model developed by Jöreskog (1970) can then be used to estimate reliabilities. To obtain four separate reliabilities from six correlations, it is also necessary to assume that the betas that represent the regression of the true score at Time t on the true score at Time $t - 1$ remain constant. This coefficient was estimated to be .955 for Listening and .968 for the intellectual composite. The estimated reliabilities appear in Table 5. (Also shown are the specific variances that are required later.) With these reliabilities the fit of the simplex to the observed intercorrelations of Listening and the composite, respectively, is excellent. The largest residual for the former is .008 and for the latter .001, and $\chi^2(1) = .80$ and .14, respectively. The reliabilities needed for the diagonal factoring appear to be highly dependable.

Since Listening has the possible causal role in this analysis, the diagonal factoring for this measure starts with Grade 5 and proceeds through Grade 11. Since the lag time between changes in the rank order of persons on Listening and on the composite is unknown, and in the absence of a theory that could guide the choice, the diagonal factoring for the composite uses both Lag 1 and Lag 2. These factors are shown in Table 6.

Although in one sense a digression, a brief discussion of the nature of diagonal factors and factor loadings when reliabilities are inserted in the principal diagonal of the R matrix may be in order. The first factor extracted represents the true score variance of the variable measured on that particular occasion. The factor loadings represent correlations of the fallible measures with this factor. The second factor extracted represents the residual true score variance of the variable measured on the occasion once removed from the one that defined the first factor. The second factor loadings are correlations between residual fallible scores and the residual true score. The factor matrices are not identical with those that would be obtained from R matrices corrected for attenuation with unities in the diagonal. Factor loadings of fallible measures are used to estimate the fallible cross-correlations between Listening and the intellectual composite.

Before proceeding with the matrix multiplication it is necessary to estimate the non-

Table 6
Diagonal Factors in Listening and the Composite

Grade	Listening				Composite							
	1	2	3	4	1	2	3	4	1	2	3	4
5	.862	.000	.000	.000	.243	.937	.000	.000	.243	.231	.908	.000
7	.863	.269	.000	.000	.000	.990	.000	.000	.000	.247	.959	.000
9	.788	.264	.249	.000	.000	.947	.245	.000	.000	.000	.978	.000
11	.731	.228	.217	.245	.000	.921	.237	.207	.000	.000	.951	.207

Table 7
Predicted Cross-Correlations Between Listening and the Intellectual Composite in Grades 5, 7, 9, and 11

	Composite											
	2-year lag				4-year lag				3-year lag			
Listening	5	7	9	11	5	7	9	11	5	7	9	11
5	.764	.806	.771	.750	.740	.782	.797	.775	.752	.794	.784	.763
7	.765	.807	.834	.812	.741	.782	.798	.828	.753	.795	.830	.808
9	.706	.746	.776	.804	.685	.723	.738	.769	.696	.735	.770	.747
11	.662	.700	.723	.747	.642	.678	.691	.718	.653	.689	.719	.742

Note. For the 2-year lag, $\Sigma d = -.211$ and $\Sigma d^2 = .006793$; for the 4-year lag, $\Sigma d = -.041$ and $\Sigma d^2 = .006089$; for the 3-year lag, $\Sigma d = -.103$ and $\Sigma d^2 = .003513$.

error specifics in the Listening test and in the composite. Specific variances for each of the 16 tests were estimated by subtracting the squared multiple correlation between an individual test and the other 15 from the estimated reliability of the test. This was, of course, done at each grade level. The four values of s^2 for Listening, which are presented in Table 5, determined their obverses, the four entries in the H matrix, by means of the relationship $h = (1 - s^2)^{\frac{1}{2}}$. Specific variances of the composite at the four grade levels were set at zero on the basis of the size of the specifics of the individual tests in the composite relative to their reliabilities. As communalities and reliabilities are increased to those for a test 15 times as long as any one component, the communality of the composite approaches very closely its reliability, which in turn approaches unity. Because the intercorrelations are high, specifics tend to be much smaler than measurement error. The result is that specific variance in the composite is trivial in size. It is seen in Table 5 that with an increase in grade and age there is a decrease in the estimated specificity of Listening.

The results of these multiplications are presented in Table 7 for Lag 1 (2 years), Lag 2 (4 years), and an approximation[3] to what a 3-year lag would have produced if the data had been available. In the note underneath the table are descriptive statistics of goodness of fit, namely, the algebraic sum of deviations and the sum of squared deviations between obtained and estimated values for all of the cross-lagged correlations. The discrepancies between obtained and predicted synchronous correlations in the diagonal are ignored in the summations because the model requires a correction for the correlated measurement error that inflates these correlations. These components cannot be estimated independently, at least for the present.

In the absence of a statistical test of goodness of fit one can only conclude that none of the three lags provides a really poor fit and that the approximation to a 3-year lag is clearly the most accurate of the three in terms of the size of the squared deviations. The 4-year lag, on the other hand, is the most accurate in terms of the size of the constant error. The negative sign of this quantity indicates that the model overestimated the observed correlations. If greater weight is placed on the squared deviations as a measure of goodness of fit, and, as a result, the 3-year lag is selected as the most likely one, there are two possible explanations for the constant error. Specific variances may have been slightly underestimated in Listening or in the intellectual composite. Values for the

[3] The equivalent of the first factor that might have been extracted at a 3-year lag if the tests had been administered was obtained by taking the square root of the mean squared factor loadings on the initial factor extracted for the 2- and 4-year lags. From these all other factor loadings can be determined. The resultant is a factor matrix of five columns from which the first two are dropped and a column of zeros added for purposes of the final matrix multiplication.

latter, it will be remembered, were set equal to zero. There is, however, a clear-cut choice between a zero lag and one of from 2 to 4 years. For the former, $\Sigma d = -.24036$ and $\Sigma d^2 = .015351$. In all probability, then, the lag between changes in individual differences in Listening and in the intellectual composite is between 2 and 4 years during the developmental period represented in these data.

We have no theory to support a possible lag of 3 years between individual differences in aural comprehension and in an intellectual composite that both requires reading and includes widely assorted information. The reading disability literature, briefly reviewed by Atkin et al. (1977b), is perhaps relevant. Also, if one accepts extrapolation as a low-level form of theorizing, it seems reasonable to assume that the 4- or 5-year lag between aural and visual comprehension of language between the ages of 2 and 6–7 becomes smaller with increasing age and education. It is surprising, as a matter of fact, to find that the lag remains as great as it seems to be in these data, which cover the period between age 11 and age 17.

It is more difficult to be specific with respect to possible causal inferences that might be drawn from the cross-lagged difference and the model that describes it. It is possible that long-term, continuing experimental manipuation of attentive behavior would affect scores on the Listening test with zero lag and have an effect on scores on the intellectual composite about 3 years later. It is also possible, however, that the causes of change in Listening are beyond any experimental manipulation in any one generation and that these more basic causes affect test scores that require visual comprehension about 3 years after the effect on Listening. It does seem safe to conclude that Listening taps the causes of intellectual development about 3 years earlier than the usual printed intellectual tests between Grade 5 and Grade 11 whether changes in Listening are directly causal or merely anticipate other effects.

The discrepancies in the diagonal would be adequately described by correlated error factor loadings of about .20. These loadings do not seem large relative to the dozen or so possible sources that can be named offhand. These sources are especially potent when testing is done in groups widely scattered geographically with several different test administrators and at somewhat different dates. The test administrators, the examinees, and the measurement settings represent classes of possible sources. Unfortunately, no independent estimate of their impact is available. For the present their assessment is completely circular; that is, they are assessed through discrepancies between estimates and observations.

Inferences From the Model

The simplex process model was introduced by means of an arbitrary example in which stationarity was observed for the two variables and for the four occasions by fixing the correlation between all true scores for adjacent occasions at .96. When the model was applied to data that involved the Listening test and an intellectual composite, the estimate of this correlation for Listening was .955 and for the composite was .968, which represented only a small departure from stationarity. Also, to obtain unique estimates of the reliabilities of the measures on each occasion, it was necessary to assume stationarity of true score regressions from occasion to occasion; that is, stationarity was forced on us by the limitations of the data.

The model is, however, more general than the above discussion indicates. Five occasions would allow estimation of two regressions of one occasion on another. Extrapolation would be required for the other two, but this would be less arbitrary than equating all at the same level. Also, the near equality of the true score regressions for the two variables was not required. The model allows for differences. For example, if correlations of .96 and .94 for X and Y, respectively, had been assumed for the original illustration, a zero time lag would not have produced a symmetrical matrix of cross-correlations. The necessary intercorrelations, factors, and cross-correlations are shown in Table 8: R_y is on the left, F_{y1} is in the center, and $F_x F'_{y1}$ is on the right. Although there are numerical differences between the cross-lagged correlations, these are spurious, being produced by

Table 8
Effects of Reducing the True Score Correlation Between Occasions of Variable Y

Occasion	Intercorrelation 1	2	3	4	Diagonal factor 1	2	3	4	Cross-correlation (zero lag) 1	2	3	4
1	1.000	.940	.884	.831	1.000	.000	.000	.000	1.000	.940	.884	.831
2	.940	1.000	.940	.884	.940	.341	.000	.000	.960	.998	.938	.882
3	.884	.940	1.000	.940	.884	.320	.341	.000	.922	.958	.996	.937
4	.831	.888	.940	1.000	.831	.302	.320	.341	.885	.920	.957	.995

the lack of stationarity from X to Y. The diagonal factoring describes accurately the amount of change from one occasion to another for each variable independently of the other and therefore takes into account the departures from stationarity.

Although stationarity is not required by the model, one must be able to estimate reliabilities and specificities. To fit both intercorrelations and cross-correlations, separate estimates are required. If one is interested only in the cross-correlations, only uniqueness estimates are necessary. With four occasions, reliabilities are estimated from intercorrelations with only one degree of freedom. With less than four occasions reliabilities must be estimated independently of the intercorrelations. Since a simplex process is presumably involved, correlations between any two occasions when corrected for attenuation must be less than unity. Estimation of specificity is a more difficult problem. If there are only two variables, estimates will likely be quite inaccurate. The two synchronous correlations furnish the only information concerning specificity and its obverse, communality.

Stationarity from occasion to occasion may be a reasonable assumption for a great many data, but it is probably unreasonable during periods of rapid development of the organism. Over a long enough time span off-diagonal correlations will probably show a pattern of increasing size. Stationarity from one measure to another is likely to be less tenable, since growth even in related functions can be at different rates. Kenny's (1975) discussion of the problem, as viewed from the present model, misplaces the emphasis. Knowledge of reliability and specificity is primary; stationarity is required for a particular method of correcting for changes in uniqueness. The correction for uniqueness he describes is entirely adequate if the simplex process is stationary for both variables and occasions. Lacking stationarity, however, residual differences will be in part spurious.

The present model also provides insight into the selection of variables to be used in a cross-lagged analysis. The measures must not only be reliable but they must have something in common. One is entitled to be uneasy about the cross-lagged comparisons in Eron, Huesmann, Lefkowitz, and Walder (1972), even though the two cross-correlations differ significantly from each other. In their data the synchronous correlations are too close to zero for any feeling of comfort, and the larger of the two cross-lagged correlations is still quite small. Their measures appear to be highly unreliable, highly specific, or both. There is, however, a mitigating circumstance. Only two time periods were represented, and these were 10 years apart. One additional intermediate occasion would be required as a minimum to resolve these doubts. Although one can say with confidence that no correlation in a simplex matrix should ever be zero, over extended periods of time some of the correlations among measures of moderately stable traits will closely approach zero.

Notice on Author Alterations

Effective January 1979, the procedure for billing authors for alterations will change. Authors of articles in APA journals are customarily charged for alterations on proofs that result from (a) authors' errors or omissions in the manuscript and (b) changes that result from authors' failure to review the edited manuscript or the proof. Until now, alteration charges have been determined by the number of lines affected by changes requested and have been based on 1974 printing rates. Beginning with the proofs for the first issues of 1979, authors' alterations will be determined not only by the number of lines affected but also by the number of figures and pages affected and will be based on current printers' rates.

This change in alteration billing is being made so that alteration charges will more closely reflect the actual cost of changes requested and may mean larger alteration bills for some authors. Authors are reminded that alteration charges apply only when changes are made of proofs and that *there is no charge* for changes made at the manuscript stage.

The Continuing Misinterpretation of the Standard Error of Measurement

Frank J. Dudek
University of Nebraska–Lincoln

Monographs, texts, and guides designed to inform readers about the meanings and interpretations of test scores frequently misinform instead, because the standard error of measurement is misapplied. The standard error of measurement, $\sigma_1(1-r_{1I})^{\frac{1}{2}}$, is an estimate of the variability (i.e., the standard deviation) expected for observed scores when the true score is held constant. To set confidence intervals for true scores given an observed score, the appropriate standard error is that for true scores when observed scores are held constant and estimated by $\sigma_1[r_{1I}(1-r_{1I})]^{\frac{1}{2}}$; and the interval is around the estimated true score rather than around the observed score. Except in the case of perfect reliability, the estimated true score is not the observed score, but is a value regressed toward the mean.

The standard error of estimate, termed the *standard error of measurement* (i.e., $\sigma_{1\infty}$, where the subscript 1 indexes an observed test score and ∞ indexes a presumed *true score* and the order of the subscripts implies that X_1 is predicted from X_∞), seems frequently to be misapplied because many sources tend to promote the erroneous notion that an interval $X_1 \pm \sigma_{1\infty}$ includes the true scores of approximately two thirds of those obtaining scores of X_1 (Educational Testing Service, 1977, p. 16; Lemke & Wiersma, 1976, p. 79; McLaughlin, 1964, p. 18).

A common model (Guilford, 1936, p. 413) for representing the variables involved when observed scores, true scores, and reliability are of concern can be represented by $X_1 = X_\infty + e$ and $X_I = X_\infty + E$, where X_1 and X_I indicate observed scores (e.g., on alternate forms of a test), X_∞ indicates a true score value underlying the observed scores, and e and E represent errors of measurement. It is assumed that (a) true and error components are independent so that $r_{e\infty} = r_{E\infty} = r_{eE} = 0$, (b) the expected value of error components is zero, and (c) $\sigma_e^2 = \sigma_E^2$. As σ_e^2 and σ_E^2 are measures of error variance, the square root of this variance is the standard error of measurement, $\sigma_{1\infty}$, defined above. Under this model it follows that $\sigma_1^2 = \sigma_I^2 = \sigma_\infty^2 + \sigma_{1\infty}^2$; that is, the observed variance of a set of test scores is made up of true variance and error variance. Reliability is given by $r_{1I} = \sigma_\infty^2/\sigma_1^2$ and indicates the proportion of observed score variance that is true variance.

The point that needs to be made about observed scores, true scores, and reliability is that one must distinguish between three different standard errors of estimate, each associated with one of three prediction situations that might be considered. Using deviation scores (i.e., $x = X - M_X$) for simplicity, using $\hat{x}$ to indicate a predicted value, and noting that $r_{1I} = r_{1\infty}^2$, the three standard errors of estimate and the associated prediction to which each applies are

$$\sigma_{1\infty} = \sigma_1(1 - r_{1\infty}^2)^{\frac{1}{2}} = \sigma_1(1 - r_{1I})^{\frac{1}{2}}: \quad \hat{x}_1 = x_\infty. \quad (1)$$

$$\sigma_{\infty 1} = \sigma_\infty(1 - r_{1\infty}^2)^{\frac{1}{2}} = \sigma_1[r_{1I}(1 - r_{1I})]^{\frac{1}{2}}: \quad \hat{x}_\infty = r_{1I}x_1. \quad (2)$$

$$\sigma_{1I} = \sigma_1(1 - r_{1I}^2)^{\frac{1}{2}}: \quad \hat{x}_1 = r_{1I}x_I. \quad (3)$$

The interpretations of all standard errors

Requests for reprints should be sent to Frank J. Dudek, Department of Psychology, 229 Burnett Hall, University of Nebraska, Lincoln, Nebraska 68588.

are analogous; thus, assuming homoscedasticity, (a) $\sigma_{1\infty}$ is the standard deviation of observed scores if the true score is held constant, (b) $\sigma_{\infty 1}$ is the standard deviation of true scores if the observed score is held constant, and (c) σ_{1I} is the standard deviation of X_1 scores if X_I scores are held constant. (It can also be noted that $\sigma_{1I}^2 = \sigma_{1\infty}^2 + \sigma_{\infty 1}^2$.)

The standard error of measurement is commonly reported along with estimates of r_{1I}, and it is important to do so because $\sigma_{1\infty}^2$ is a measure of the amount of error variance that obtains in a set of observed scores. Furthermore, $\sigma_{1\infty}$ as an indicator of measurement error tends to stay constant across populations, whereas r_{1I} varies in magnitude depending on the heterogeneity (i.e., range of talent) represented in the group. Both the reliability coefficient and the standard error of measurement provide useful, descriptive information.

But the interpretation that an interval that extends one standard error of measurement above and one standard error of measurement below an obtained score will include the true scores of approximately two thirds of the individuals who received this obtained score (as implied in the references cited earlier) is in error. The reason is that the prediction implied here is that of a true score *given* an obtained score, and as noted by the prediction in Formula 2, the predicted value of the true score is not the observed score itself, but is an estimate regressed toward the mean. The appropriate standard error of estimate in this situation would be $\sigma_{\infty 1}$, not $\sigma_{1\infty}$.

To illustrate for a set of values in which $\mu_1 = \mu_I = 500$, $\sigma_1 = \sigma_I = 100$, and $r_{1I} = .90$, one finds $\sigma_{1\infty} = 31.623$, $\sigma_{\infty 1} = 30.00$, and $\sigma_{1I} = 43.589$. For all persons who scored 700 on this test, we would infer that the average (i.e., predicted) true score for these persons is 680 and that about two thirds of their true scores lie in the interval 680 ± 30, or between 650 and 710. (On a retest of these individuals one would expect to find two thirds of their retest scores in the interval 680 ± 43.6.)

Standard reference texts (e.g., Guilford, 1936, 1954; Lord & Novick, 1968; Nunnally, 1978) either make or imply the distinctions, of course; but their cautions, caveats, and admonishments are often unheeded, ignored, or misinterpreted in the applied literature.

Guilford (1936) included a footnote:

> Too often one finds the interpretation of a $\sigma_{1\infty}$ misstated. For a given score of 50 when $\sigma_{1\infty}$ is 4, one is likely to read the interpretation that "the probability is two-thirds that the true score lies between 46 and 54." The latter statement implies the prediction of X_∞ from X_1. (p. 414)

On the next page he suggested, "It is correct practice to speak of $\sigma_{1\infty}$ as the *standard error of a raw score* and of $\sigma_{\infty 1}$ as the *standard error of a true score*" (p. 415).

Lord and Novick (1968, pp. 67–68) provided formulations equivalent to our three formulae for the three standard errors of measurement and suggested naming the various standard errors as (a) the standard error of measurement, (b) the standard error of estimation, and (c) the standard error of prediction.

Nunnally (1978), in discussing the standard error of measurement, emphasized that

> One can use it to set confidence zones for obtained scores, but in so doing one must understand that such confidence zones *are not symmetrical about the obtained score*. Thus, although it usually is done in practice, it is incorrect to set the 95 percent confidence zone as equaling two standard errors of measurement below and two above the obtained score. (p. 218)

The first reference to scores in this quotation should have been to true scores rather than to obtained scores. Using the standard error of measurement in the situation in which true score intervals are inferred from obtained scores will not lead to serious error (providing, of course, that regression is taken into account), inasmuch as the standard error in Formula 2 will be less than the standard error in Formula 1 although their values are reasonably close to one another when reliability is high, as seen in the illustration above. Using the standard error in Formula 1, then, even though the standard error in Formula 2 is appropriate will lead to a somewhat liberal interval. But if one desires to set confidence intervals for obtained scores (say on a retest), then the appropriate standard error is σ_{1I}, and using the standard error of measurement in such a situation could lead to a serious underestimation of the interval.

In summary, the standard error of measure-

ment is an estimate of the variability (i.e., standard deviation) of observed scores given a true score and is clearly inappropriate for the situation in which one sets confidence limits for true scores given a fallible, obtained score. For the latter situation one requires the standard deviation of true scores when the observed score is held constant. This standard error is indicated by Formula 2. Equally important is to recognize that the estimated true score, given an observed score, is a value regressed toward the mean, and any confidence interval for true scores will be symmetrical around this regressed value for the true score, not around the observed value.

Detecting Cyclicity in Social Interaction

John M. Gottman
University of Illinois at Urbana-Champaign

This article reviews spectral and cross-spectral analytic methods for detecting cyclicity, cross-cyclicity, and lead–lag relationships in continuous data derived from the observation of dyadic interaction. It is found that lead–lag relationships can be assessed using the phase spectrum. Spectral analytic methods are then generalized to categorical observational data, and it is shown that by these methods one can derive the classical information theory definition of social communication and its distribution statistics.

Researchers who study social behavior are discovering that there are occasions when cyclical patterns characterize dyadic interaction, and thus they are searching for statistical techniques that can detect these cycles. The spectral analysis of time-series records was briefly suggested by Luce (1970) as a useful technique for the study of biological rhythms such as heart rate, respiration, REM sleep, and other cyclic biochemical and physiological processes. However, spectral analysis is not widely known to behavioral scientists, and it has yet to be used in the study of social interaction. A recent exception is the work of Hayes and Cobb (Note 1), who observed couples living in a laboratory setting, analyzed cycles of talk and silence using spectral analysis of time-series records, and related an observed cycle to human circadian rhythms.

Researchers who study dyadic social interaction are also interested in the bivariate case in which two time-series records are obtained, one from each of the two interacting organisms; the research question often involves the search for cycles in cross-correlations between the two series. For example, Kendon (1967) reported that when two people converse, the cycles of gaze and gaze aversion interlace, much as do sine and cosine waves. People are out of phase in eye-to-eye contact as a function of who is speaking; in particular, when a person begins speaking he or she looks away from the listener and begins increasing eye-to-eye contact time toward the end of the speech, which acts as an implicit signal for the listener to begin looking away and speaking.

Another example of cross-cyclicity is the work of Brazelton and his associates (e.g., Brazelton, Koslowski, & Main, 1974). Tronick, Als, and Brazelton (1977) studied mother–infant interaction and reported that the infants looked away following periods of maximum involvement with the mother and after a rest period became engaged again. Tronick et al. calculated synchrony and dissynchrony as running correlations between scaled scores of involvement, from maximum positive involvement to maximum negative involvement, but did not employ cross-spectral time-series methods. Cross-spectral analysis would have been an appropriate technique for studying both synchrony and lead–lag relationships between two time series in the Tronick et al. study.

Cross-spectral analysis may have considerable promise for studying interacting physiological systems within an organism. For example, Porges and his associates (Porges, Bohrer, Keren, Cheung, & Franks, Note 2) are using cross-spectral methods to study the linkage between respiration and heart rate. A function called *coherence* obtained from cross-spectral analysis is the equivalent of the

square of the correlation between the two physiological systems as a function of their relative lag. Porges et al. found that the coherence between respiration and heart rate is related to cognitive attentional processes. Hyperactive children had low coherence between respiration and heart rate; low doses of methylphenidate had positive influence on cognitive performance and social behavior, whereas higher doses often resulted in lethargy. Porges and his associates are testing the model that deficits in linkage between the respiratory system and the cardiovascular systems are related to the attentional problems of hyperactive children and that low doses of methylphenidate mediate to increase the coherence between systems, thereby affecting cognitive functioning.

Because time-series techniques are not widely known to psychologists, this article reviews the spectral and cross-spectral analysis of continuous data. The present research also derives the new result that the slope of the phase spectrum of any two stationary processes can be used to detect lead–lag relationships. Lead–lag relationships are useful in making inferences about which series is, in some sense, driving the other. One application of lead–lag relationships is a redefinition of the concept of dominance in social interaction as an asymmetry in predictability in the time domain (Gottman, in press). This definition of dominance using cross-spectral analysis subsumes a range of observations about dominance across species. For example, the beta male in a group of monkeys is more responsive to the behavior of the alpha male than conversely (Maslow, 1936); that is, the behavior of the beta male is more predictable from past behavior of the alpha male than conversely.

Most researchers of social interaction collect categorical rather than continuous observational data (e.g., Hutt & Hutt, 1970; Lewis & Rosenblum, 1974). There are currently no statistical techniques for detecting cycles in one sequence and cycles between two sequences for categorical data over time. Categorical data collected over time can always be transformed to continuous time-series data; for example, for every block of k time units the local probability of each category can be computed, which produces a continuous variable for each category. For a discussion of categorical data types in observational research, see Gottman and Bakeman (in press).

In this article, I derive extensions of spectral time-series methods to categorical data. One result of these extensions is the derivation of the commonly used information theory definition of communication, summarized by Wilson (1975) as follows:

> Communication has been defined as the process by which behavior of one individual alters the probability of behavioral acts in other individuals . . . . In words, the conditional probability that act X_2 will be performed by individual B given that A performed X_1 is not equal to the probability that B will perform X_2 in the absence of X_1. (p. 194)

This is an important definition for the study of sequences in social interaction because it suggests the notion that a behavior in one organism has social communicative value to the extent that it reduces uncertainty in predicting the behavior of another organism. This definition is now widely used to detect sequences in dyadic interaction (for reviews, see Gottman & Bakeman, in press; Gottman & Notarius, 1978; Sackett, 1977).

Another result of the extension of spectral time-series methods to categorical data in this article is the demonstration of the validity (and limitations) of a statistical test of significance between conditional and unconditional probabilities recently suggested by Sackett (1977). After the information theory definition of communication is derived, spectral and cross-spectral methods are used to suggest how lead–lag relationships and cycles can be detected in categorical time series.

The Continuous Case

Granger and Hatanaka (1964) noted that the first time series subjected to spectral analysis were those that had a cycle with one dominant frequency, such as the 11-year oscillation in sunspot data and the annual cycle in meteorological data. They wrote,

> It was felt that if one could determine the amplitude period and phase of a sine curve sufficiently accurately and subtract this from the data, then the remainder ought to be an independent, random series. When, in fact, this was done and the remainder was still found to be somewhat too smooth, it was natural to re-use the current predominant idea of the cause of the

smoothness and to look for yet further sine curves to fit to the data. (pp. 4–5)

The model for a time series, X_t, was therefore a weighted sum of sine and cosine curves with an uncorrelated random remainder; if the number of observations, $n = 2q + 1$, is odd, one can write

$$X_t = A_0 + \sum_{i=1}^{q} (A_i \cos 2\pi f_i t + B_i \sin 2\pi f_i t) + \epsilon_t, \quad (1)$$

where $f_i = i/n$ is the ith harmonic of the fundamental frequency $1/n$. Fourier analysis makes it possible to derive least squares estimates for the coefficients:

$$\hat{A}_0 = \bar{X} = \frac{1}{n} \sum X_t;$$

$$\hat{A}_i = \frac{2}{n} \sum_{t=1}^{n} X_t \cos 2\pi f_i t;$$

$$\hat{B}_i = \frac{2}{n} \sum_{t=1}^{n} X_t \sin 2\pi f_i t.$$

This decomposition of a time series into component frequencies met with some initial success. For example, Whittaker and Robinson (1924) showed that the brightness of a variable star could be decomposed into two component frequencies, and they thus determined that the variable star was a binary star.

It would be useful to have some function that peaked at frequency bands that made major contributions to the variance of the series. For an infinite number of observations, the variance of the series at each frequency, f_i, is called the spectral density function, f. For a sample of n points it is called the *periodgram:* $I(f_i) = (1/8\pi)(A_i^2 + B_i^2)$. Because the sine and cosine terms in Equation 1 form an orthogonal set of functions, it can be shown that the variance of the time series is partitioned into independent parts by the periodogram:

$$\frac{1}{n} \sum (X_t - \bar{X})^2 = \frac{1}{2n} \sum I(f_i).$$

Early work on the spectral analysis of time series suggested that the periodogram was precisely the function that would peak at frequencies that contributed major portions to the variance of the time series; in fact, Schuster (1898) suggested that the periodogram be calculated and that its peaks be used to detect cycles. Subsequently, problems with spurious peaks led to the construction of significance tests for the periodogram (for a review of these tests, see Jenkins & Priestley, 1957). However, these tests were not adequate because the periodogram has some very poor statistical properties.

If the sample autocovariance at lag k is defined as

$$C_k = \frac{1}{n} \sum_{t=1}^{n-k} X_t X_{t-k},$$

then C_k is an unbiased estimator of the population autocovariance (Hannan, 1967), and it can be shown (Box & Jenkins, 1970, p. 45) that the periodogram is given by

$$I(f) = \frac{1}{2\pi}(C_0 + 2 \sum_{k=1}^{n-1} C_k \cos 2\pi f k),$$

where $0 \leq f \leq \frac{1}{2}$, which expresses that the periodogram is the Fourier transform of the sample autocovariance function. This implies that the periodogram is also easily calculated from the sample autocovariances; thus at first the problems of spectral time-series analysis appeared to be solved.

Unfortunately, although the periodogram does converge to the spectral density function, f, it does not converge uniformly; that is, its variance around f does not decrease to zero as n, the number of observations, increases (Hannan, 1967, pp. 52–53). In fact, Bartlett (1948) showed that the limit of the variance of the periodogram as n increases is $\sigma^4 f^2$, where σ^2 is the variance of the series. The failure of the periodogram led Tukey (1967) to make the following reflection:

> If we dealt with problems involving the superposition of a few simple periodic phenomena, as do astronomers interested in binary stars and related problems, we can learn much from the periodogram. Sadly, however, almost no one else has this kind of data. As a result the periodogram has been one of the most misleading devices I know. (p. 25)

A dramatic illustration of Tukey's point is the periodogram of a series of random numbers, called white noise. White noise, like white light, is composed of all frequencies with equal intensities, and therefore its periodogram should be a straight line. Jenkins and Watts (1968) showed that the periodogram of white

noise is not only not a straight line but continues to oscillate wildly as the number of observations is increased. However, the spurious peaks of the periodograms of each sample of white noise occur in random places on the frequency domain, and this provides the key to solving the problems of the periodogram. The average of many periodograms obtained from many samples of the same white noise process in fact tends toward a straight line as the number of observations in each sample increases.

This observation led Bartlett (1948) to suggest that the time series can be segmented and that a periodogram can be averaged across all segments. Bartlett showed that the averaged periodogram would coverage uniformly to the spectral density. Jenkins (1967) demonstrated that Bartlett's suggestion is equivalent to estimates of the form

$$f(f_i) = \frac{1}{2\pi}\left[C_0 + 2\sum_{j=1}^{n-1} \lambda_j(f_i)C_j \cos 2\pi f_i j\right]. \quad (2)$$

The function of $\lambda(f_i)$ is called a *spectral window*, and it weights the autocovariance function to ensure uniform convergence. Parzen's (1967) result is important because to implement Bartlett's suggestion would require an extremely long time series, whereas Jenkins's suggestion can be implemented with shorter time series, assuming that the window weighting function is suitably chosen. The most commonly used spectral window is the Tukey–Hanning window (Blackman & Tukey, 1958): $\lambda_j = 1 + \cos(\pi j/m)$, where m is an arbitrary integer, usually chosen so that $m < n/3$. (See Parzen, 1967, for a discussion of various spectral windows.) Thus a weighted Fourier transform of the autocovariance function does converge uniformly to the spectral density. Jenkins and Watts (1968) showed that the distribution of the intensity estimates at each frequency of the periodogram "will be very nearly a χ_2^2 regardless of the distribution of the [time-series] process" (p. 233). For the Tukey–Hanning window, the equivalent degrees of freedom must be modified (Granger & Hatanaka, 1964, pp. 59–64; Jenkins & Watts, 1968, pp. 248–257). In this article the term *spectrum* refers to the weighted periodogram.

An illustration of the spectrum may clarify its relationship as the Fourier transform (with an appropriate spectral window) of the autocovariance function. If the time series is a second-order autoregressive process,

$$X_t = \phi_1 X_{t-1} + \phi_2 X_{t-2} + \epsilon_t, \quad (3)$$

where ϵ_t is an uncorrelated, random series and $\phi_1^2 + 4\phi_2 < 0$, then the behavior of the series will appear periodic. The constraints on ϕ_1 and ϕ_2 occur because periodicity only occurs when the roots of the characteristic equation of the process are imaginary (Box & Jenkins, 1970, p. 59). Note that this time series will not be deterministically periodic, as is a sine wave; there is a random component to the periodicity. In this case the autocovariance function will be a single-frequency damped sine wave.[1] Figure 1 is a plot of the autocorrelation function and spectrum of a simulated second-order autoregressive model. The spectrum shows only one peak[2]; a fourth-order autoregressive process is capable of representing a process with two peaks, and so on.

The relationship between the autocorrelation and spectrum of the process represented by Equation 3 is intuitively clear. If the time series is periodic, the autocorrelation should increase at multiples of the period. For

---

[1] The expression for the theoretical autocorrelation function is

$$\rho_k = \frac{[\text{sgn}(\phi_1)]^k d^k \sin(2\pi f_0 k + F)}{\sin F},$$

where sgn $= +1$ if ϕ_1 is positive and sgn $= -1$ if ϕ_1 is negative. The factor d is called the *damping factor*, f_0 is called the *frequency*, and F is called the *phase*. These factors are related to the model parameters as follows:

$$d = [(-\phi_2)^{\frac{1}{2}} \text{sgn}(\phi_1)];$$

$$\cos 2\pi f_0 = \frac{|\phi_1|}{2(-\phi_2)^{\frac{1}{2}}};$$

$$\tan F = \frac{1+d^2}{1-d^2}\tan 2\pi f_0.$$

[2] The spectrum of a second-order autoregressive process can be written in closed form as

$$p(f) = 2\sigma_a^2/[1 + \phi_1^2 + \phi_2^2 - 2\phi_1(1-\phi_2)\cos 2\pi f - 2\phi_2 \cos 4\pi f],$$

where $0 \le f \le \frac{1}{2}$. The spectrum reflects the periodic behavior of the second-order autoregressive process when the roots of its characteristic equation are complex.

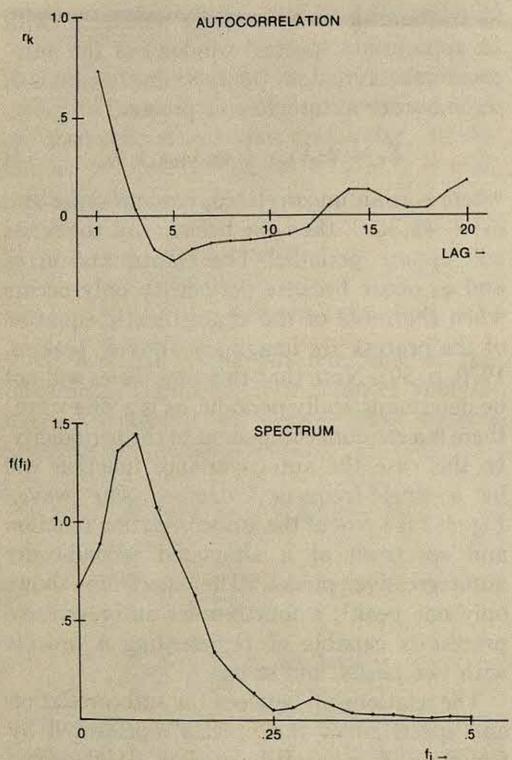

Figure 1. Autocorrelation function (r_k is the autocorrelation at lag k) and spectrum, $f(f_i)$, of one realization of a second-order pseudoperiodic time series. ($X_t = 1.1X_{t-1} - .5X_{t-2} + e_t$.)

example, for monthly wholesale wheat prices, the correlation between months 12 months apart (June with June, July with July, etc.) should be higher than that between months in different seasons. This relationship should fall off across years, and so the autocorrelation should resemble the damped sine wave in Figure 1. Since there is only one 12-month cycle, one would expect the spectrum (the weighted Fourier transform of the autocovariance function) to show only one peak. If the series had two cycles, the autocorrelation function would appear similar in shape (but more complex), and the spectrum would have two peaks.

Note that one cannot reconstruct the original time series simply by knowledge of the spectrum. This is true because very different series can be produced simply by adjusting the relative phases of the component frequencies; the phase of a sine wave determines its amplitude at time zero. Phase is a particularly important concept in the bivariate case.

For two time series, the generalization is not difficult. In fact, the Fourier transform (with suitable window) of the cross-covariance between the two time series is the cross-spectrum. The cross-spectrum has several components, a phase spectrum, and a cross-amplitude spectrum. The phase spectrum indicates

> whether the frequency components of one series lead or lag the same frequency components in the other series, and the cross-amplitude spectrum shows whether the amplitude of the component at a particular frequency in one series is associated with a large or small amplitude at the same frequency in the other series. (Jenkins & Watts, 1968, pp. 342–343)

The coherence is a function similar to the square of a correlation coefficient and is defined as the ratio of the square of the cross-spectrum divided by the product of the spectra of the individual series[3]; for two series, X_t and Y_t,

$$K_{xy}(f_i) = \frac{|f_{xy}(f_i)|^2}{f_{xx}(f_i)f_{yy}(f_i)}. \tag{4}$$

Distribution properties of these functions are discussed in Jenkins and Watts (1968, chap. 9); the properties for these functions with the Tukey–Hanning window are discussed in Granger and Hatanaka (1964, chap. 5). A coherence of one means that prediction is perfect from one series to another for all frequencies; a coherence of zero means that it is impossible to predict one series from the other. The prediction is of amplitude covariations in the two series, with no indication of lead–lag relationships, so that a complete description of relationships requires the phase spectrum as well as the coherence. If the coherence has one major peak, then the bulk of the correlation between the two processes is confined to a particular frequency band. If it is essential to predict correlations at major frequency bands of series Y_t, the coherence can be investigated at frequencies that have peaks in the spectrum of Y_t. An

---

[3] An alternative approach for specifying the relationship between two time series in the time domain, as opposed to in the frequency domain, is called *transfer function analysis* and is discussed by Box and Jenkins (1970).

alternative, suggested by Porges et al. (Note 2), is to compute one statistic called the *weighted coherence*, which is an estimate of the amount of variation in one series that can be accounted for by variation in the other:

$$\sum_i k_{xy}(f_i) f_{xx}(f_i) / \sum_i f_{xx}(f_i).$$

They wrote,

> Conceptually the coherence may be thought of as a time-series analogue of the omega-squared . . . . or the amount of variance accounted for by the influence of one series on the other. Therefore, the coherence times the spectral density estimate of heart rate activity at each frequency . . . . would describe the amount of heart rate activity which could be accounted for by respiration, i.e., the shared variance of heart rate and respiration. (p. 5)

If the cross-covariance is $C_{xy}(t)$, the unweighted cross-spectrum is the Fourier transform of the cross-covariance:

$$f_{xy}(f) = \frac{1}{2\pi} \sum_{-\infty}^{\infty} e^{i2\pi f t} C_{xy}(t), \quad \text{where} \quad i = (-1)^{\frac{1}{2}}.$$

This complex number can be written as a real part plus an imaginary part: $f_{xy}(f) = C + iQ$. The phase spectrum is defined as

$$\phi_{xy}(f) = \arctan \frac{Q}{C}; \tag{5}$$

C is called the cospectrum and Q the quadrature spectrum, and they measure the covariance between in-phase and out-of-phase components, respectively.

The slope of the phase spectrum determines the time-lag and the lead–lag relationships between the two series. For example, if one time series, $X(t) = \epsilon(t)$, is white noise with variance σ^2 and the other series is $Y(t) = X(t + L)$, then L is the *lead time* and Y leads X by L time units later. Since $X(t)$ is white noise, the covariance of $X(t)$ and $Y(t)$ is

$$\begin{aligned} C_{xy}(t) &= E[X(s)Y(s + t)] \\ &= E[X(s)X(s + t + L)] \\ &= \begin{cases} \sigma^2 & \text{at} \quad t = -L \\ 0 & \text{otherwise} \end{cases} . \end{aligned}$$

The cross-spectrum is the Fourier transform of the cross-covariance. Assuming $\sigma = 1$, this

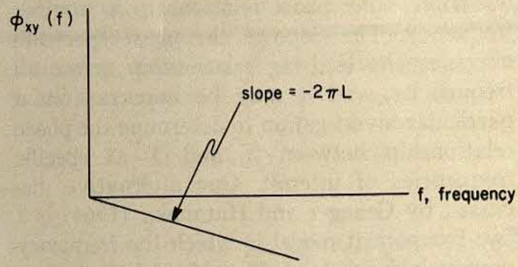

Figure 2. Phase spectrum, $\Phi_{xy}(f)$, when $Y(t)$ leads $X(t)$ by a constant time, L.

gives

$$\begin{aligned} f_{xy}(f) &= \frac{1}{2\pi} \sum_{-\infty}^{\infty} e^{i2\pi f t} C_{xy}(t) \\ &= \frac{\sigma^2}{2\pi} e^{-i2\pi f L} = \frac{\sigma^2}{2\pi} (\cos 2\pi f L - i \sin 2\pi f L), \end{aligned}$$

where $i = (-1)^{\frac{1}{2}}$. The phase spectrum is given by

$$\begin{aligned} \phi_{xy}(f) &= \arctan \left(\frac{Q}{C} \right) = \arctan \left(\frac{-\sin 2\pi f L}{\cos 2\pi f L} \right) \\ &= \arctan(-\tan 2\pi f L) = -2\pi f L. \end{aligned}$$

Therefore the phase spectrum will be a straight line that passes through the origin with negative slope proportional to the time lag, L (see Figure 2).

More generally, lead–lag relationships can be estimated by testing the significance of the slope of the least squares linear regression approximation to the phase spectrum.[4] It is important to note that this method does not give complete information; X and Y may be periodic at a particular frequency and have a constant phase relationship at that frequency

---

[4] The phase spectrum shown in Figure 2 can be shown to hold for any two stationary processes that differ by a constant time lag. If $Y(t) = X(t + L)$, then the Fourier transform of $Y(t)$ is

$$F[Y(t)] = \int_{-\pi}^{\pi} Y(t) e^{iwt} dt = \int_{-\pi}^{\pi} e^{iwt} X(t + L) dt.$$

If one lets $u = t + L$, then

$$F[Y(t)] = \int_{-\pi}^{\pi} e^{iw(u-L)} X(u) du = e^{-iwL} \int_{-\pi}^{\pi} e^{iwu} X(u) du;$$

$$F[Y(t)] = e^{-iwL} F[X(t)].$$

Hence the Fourier transform of $Y(t)$ is the Fourier transform of $X(t)$ multiplied by the phase shift $e^{-i\phi}$, where $\phi = -wL$.

but some other phase relationship at another frequency. The slope of the phase spectrum averages the lead–lag relationship across all frequencies, and it may be important in a particular investigation to determine the phase relationship between X and Y at specific frequencies of interest. One alternative discussed by Granger and Hatanaka (1964) is a two-component model in which the frequency domain is divided in half and lead–lag relationships are assessed separately for slow and rapid components. For these calculations, computer programs are available in most universities that have the University of California, Los Angeles biomedical series (Dixon, 1974, pp. 517–582, Programs 2T, 3T, and 4T).

The Categorical Case

In the categorical case two series, X_t and Y_t, are set equal to one if the characteristics that they represent are observed and equal to zero otherwise. The unbiased estimator of the cross-covariance, lagged k units in time is

$$C_{xy}(k) = \frac{1}{n-k}\sum_{1}^{n-k}(X_t - \bar{X})(Y_{t+k} - \bar{Y}).$$

For categorical data, $\bar{X}$ and $\bar{Y}$ are the unconditional probabilities, p_x and p_y, that X_t and Y_t are one in $n - k$ observations, so that

$$\begin{aligned} C_{xy}(k) &= \frac{1}{n-k}\sum_{1}^{n-k}(X_t - p_x)(Y_{t+k} - p_y) \\ &= \frac{1}{n-k}\Big[\sum_{1}^{n-k} X_t Y_{t+k} - p_y \cdot \sum_{1}^{n-k} X_t \\ &\quad - p_x \cdot \sum_{1}^{n-k} Y_{t+k} + p_x p_y (n-k)\Big] \\ &= \frac{1}{n-k}\Big[\sum_{1}^{n-k} X_t Y_{t+k} - p_y p_x (n-k) \\ &\quad - p_x p_y (n-k) + p_x p_y (n-k)\Big]; \end{aligned}$$

$$C_{xy}(k) = \frac{1}{n-k}\Big[\sum_{1}^{n-k} X_t Y_{t+k} - p_y p_x (n-k)\Big]. \quad (6)$$

The sum in Equation 6 is simply the number of lagged-k (1, 1) pairs. Note that by definition, the conditional probability that Y is equal to one given that X was equal to one k time units ago, $p_k(Y|X)$, is simply the number of (1, 1) pairs at lag k divided by the number of occurrences of $X = 1$ in $n - k$ observations. If one denotes the number of (1, 1) pairs at lag k as $M_{xy}(k)$, then, from the definition of the lagged conditional probability, it follows that $p_k(Y|X) = M_{xy}(k)/p_x(n-k)$. Therefore, the number of (1, 1) pairs at lag k is

$$M_{xy}(k) = \sum_{1}^{n-k} X_t Y_{t+k} = p_k(Y|X)(p_x)(n-k).$$

Substituting this back into Equation 6 gives

$$C_{xy}(k) = p_x[p_k(Y|X) - p_y], \quad (7)$$

as the categorical equivalent of the cross-covariance.

This function is proportional to the information theory definition of communication assessed as the difference between conditional and unconditional probabilities.

To derive the distribution of the covariance, the variance of the covariance can be computed as follows:

$$\begin{aligned} C_{xy}(k) &= p_x[p_k(Y|X) - p_y]; \\ C_{xy}(k) - \bar{C} &= p_x p_k(Y|X) - p_x \overline{p_k(Y|X)} \\ &= p_x[p_k(Y|X) - \overline{p_k(Y|X)}]; \\ \operatorname{var}[C_{xy}(k)] &= p_x^2\{\operatorname{var}[p_k(Y|X)]\}. \end{aligned}$$

Under the null hypothesis of no relationship between the two categorical time series, X_t and Y_t, $p_k(Y|X) = p_y$, and the variance of the unconditional probability of a dichotomous variable that is not autocorrelated is $p_y(1 - p_y)/m$ (Siegel, 1956, p. 40), where m = the number of observations used to calculate p_y. For the covariance $C_{xy}(k)$, $m = n - k$, and the result is

$$\operatorname{var}[C_{xy}(k)] = p_x^2 p_y(1 - p_y)/(n-k).$$

Since under the null hypothesis, $C_{xy}(k)/SD[C_{xy}(k)]$ is normally distributed with mean zero and unit variance ($N[0, 1]$) (Box & Jenkins, 1970), one has

$$\frac{C_{xy}(k)}{SD[C_{xy}(k)]} = \frac{p_x[p_k(y|x) - p_y]}{[p_x^2 p_y(1-p_y)/(n-k)]^{\frac{1}{2}}} \sim N(0, 1);$$

$$Z = \frac{p_k(y|x) - p_y}{[p_y(1-p_y)/(n-k)]^{\frac{1}{2}}} \sim N(0, 1). \quad (8)$$

This is a derivation of a statistic that was recently proposed by Sackett (1977).

An estimate of the error introduced in Equation 8 by autocorrelation in each series, under the null hypothesis of no cross-correlation, can be obtained by using the expression for the variance of the cross-correlation under the null hypothesis given by Box and Jenkins (1970, p. 377):

$$\operatorname{var}[r_{xy}(k)] \simeq \frac{1}{n-k}[1 + \sum_{j=1}^{\infty} r_{xx}(j) r_{yy}(j)]$$

$$\simeq \frac{1}{n-k}(1+\delta).$$

Thus, the variance of the cross-correlation would be $1/(n-k)$ if there were no autocorrelation. To estimate the quantity δ, rewrite the autocorrelations using

$$r_{xx}(k) = C_{xx}(k)/C_{xx}(0):$$

$$\delta = \sum_{1}^{\infty} r_{xx}(j) r_{yy}(j)$$

$$= \frac{1}{C_{xx}(0) C_{yy}(0)} \sum_{1}^{\infty} C_{xx}(j) C_{yy}(j).$$

Now substitute the quantity for the covariance from Equation 7:

$$\delta = \frac{p_x p_y}{p_x(1-p_x) p_y(1-p_y)} \sum_{1}^{\infty} [p_j(x|x) - p_x] \times [p_j(y|y) - p_y].$$

If one assumes that the quantity in the sum decreases exponentially with increasing lag and one denotes

$$\theta = [p_1(x|x) - p_x][p_1(y|y) - p_y],$$

then

$$\delta = \frac{1}{(1-p_x)(1-p_y)} \cdot \frac{\theta}{(1-\theta)}.$$

Delta is a maximum when the conditionals are one and a minimum when the conditionals equal the unconditionals:

$$\delta_{\max} = \frac{1}{1-(1-p_x)(1-p_y)}; \quad \delta_{\min} = 0.$$

The cross-spectral density function for categorical data can be written as the Fourier transform of the cross-covariance (weighted by a suitable window), and this function will behave in a fashion similar to the continuous case. The generalizations are obtained by applying Equation 2 to Equation 7: The cross-spectrum is

$$f_{xy}(f_i) = \frac{1}{2\pi}[C_{xy}(0)\lambda_0(f_i) + 2 \sum_{j=1}^{n-1} \lambda_j(f_i) C_{xy}(j) \cos 2\pi f_i j].$$

The spectrum of X_t is

$$f_{xx}(f_i) = \frac{1}{2\pi}[p_x(1-p_x)\lambda_0(f_i) + 2 \sum_{j=1}^{n-1} \lambda_j(f_i) C_{xx}(j) \cos 2\pi f_i j].$$

The spectrum of Y_t is

$$f_{yy}(f_i) = \frac{1}{2\pi}[p_y(1-p_y)\lambda_0(f_i) + 2 \sum_{j=1}^{n-1} \lambda_j(f_i) C_{yy}(j) \cos 2\pi f_i j].$$

The lambdas are the Tukey–Hanning weights (Blackman & Tukey, 1958).

To summarize, Equation 7 is the categorical equivalent of the cross-correlation, and if $X = Y$, of the autocorrelation. If cyclicity exists in a series of categorical data with one major cycle, then $C_{xy}(k)$ should behave as a damped sine wave of Figure 1, and the spectrum should show one peak. An examination of the spectrum, which is the weighted Fourier transform of Equation 7, reveals major cycles in the categorical series. The coherence and phase spectrum are similarly generalized, and the slope of the phase spectrum detects lead–lag relationships that span all component frequencies. Computationally, all these statistics can be calculated simply by inputting each series as a binary zero–one time series.

To illustrate the relationship between continuous and dichotomous spectral time-series statistics, one example that compares statistics for continuous data and the same data dichotomized around the mean is presented.

Example

The data in this example are derived from coding a videotape of a married couple working

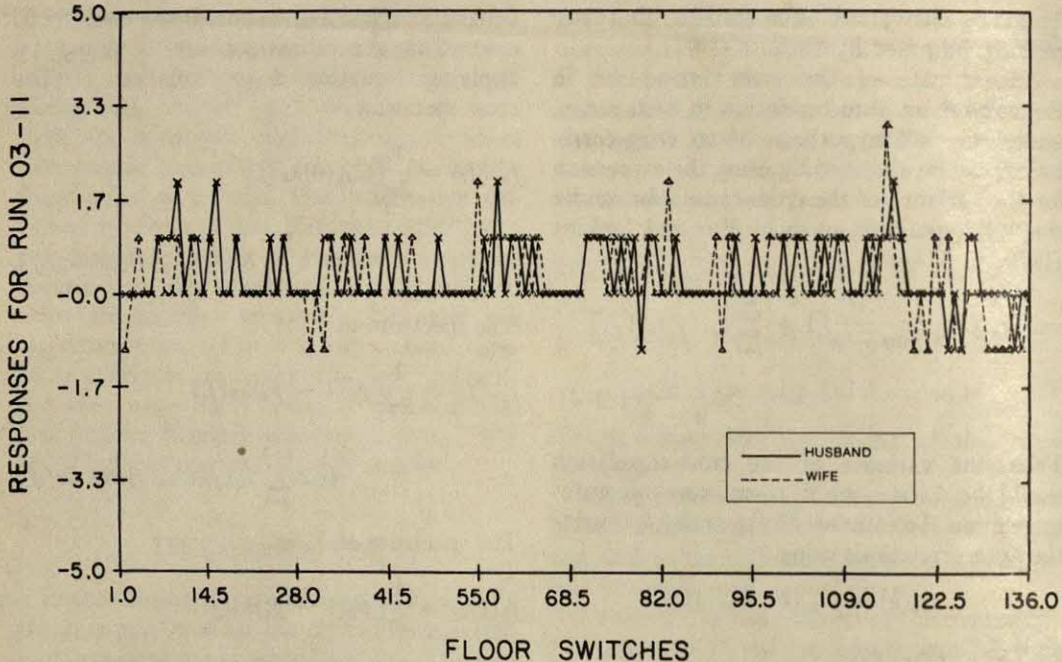

Figure 3. Positivity of behaviors of one couple on an improvised conflict task.

on an improvised conflict task. The coding system and the method for generating the time series from categorical data are described in Gottman, Markman, and Notarius (1977). The graphs displayed in Figure 3 represent a tally of positive minus negative nonverbal behavior coded from voice tone, facial expressions, and body cues. The unit plotted on the abscissa is the "floor switch," that is, the set of utterances before one person gives up the floor to the other.

These data were transformed to categorical data by dichotomizing around the mean of each series, and phase spectra and the coherences were calculated for both the discrete and the continuous cases using Tukey–Hanning

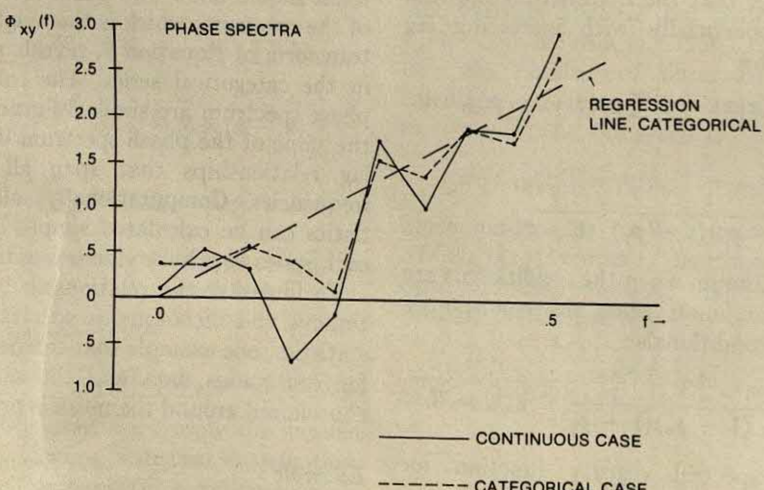

Figure 4. Phase spectra for continuous and dichotomous case of couple in Figure 3; $\Phi_{xy}(f)$ = phase spectrum; f = frequency.

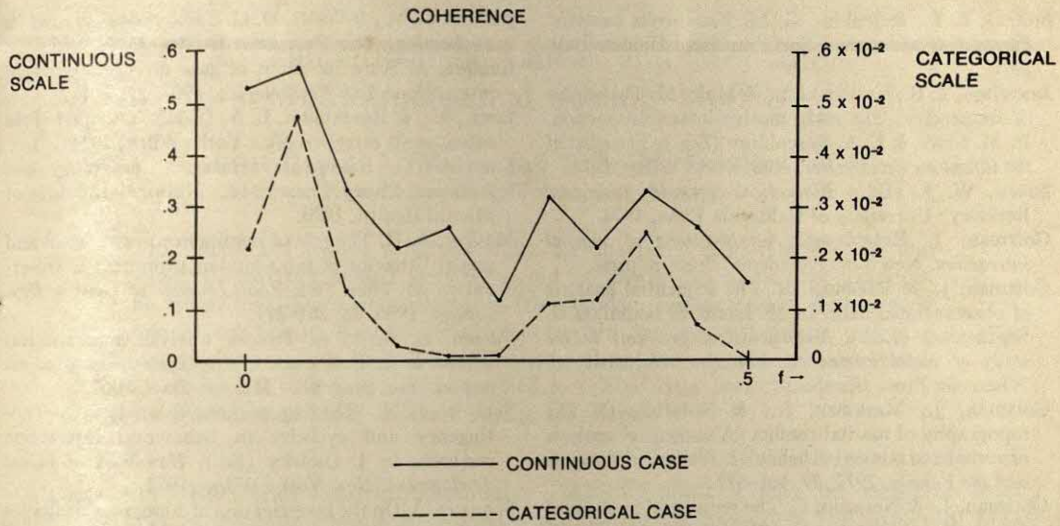

Figure 5. Coherence spectra for continuous and dichotomous cases of couple in Figure 3; f = frequency.

weights and the Fast-Fourier transform program available at the University of Illinois (SOUPAC programs). Figures 4 (see Equation 5) and 5 (see Equation 4) present a comparison of these two statistics for the continuous and categorical cases. The phase spectra are nearly identical and have very similar regression lines that in both cases are interpreted as the wife leading the husband, with a constant lag equal to the slope of the regression line. The slope is .31 for the continuous case and .25 for the categorical case.

The coherence for the categorical case is much lower, which is not surprising because so much information about strength of association is lost by dichotomizing. However, the important aspect of the coherence is the location of peaks, and one can see that the coherence for the categorical case has a shape similar to that of the continuous case. The two highest peaks (at $f = .1$ and $f = .4$) are the same for both cases, so that information about cyclicity in the strength of association across series is preserved.

Conclusion

Spectral and cross-spectral time-series methods were reviewed in this article for continuous data, and interpretations were discussed for the spectrum, the coherence, the weighted coherence, and the phase spectrum. These methods were also extended to categorical data. The extension made it possible to derive the information theory statistic for comparing conditional with lagged unconditional probabilities and for exploring the limits of the z-score test as a function of autocorrelation. Subsequent investigations should generate stochastic time-series data by using known autoregressive-moving average models with seasonal components (Box & Jenkins, 1970) and by comparing continuous and dichotomous analyses. The methods proposed in this article need to be applied to a range of problems, and their ability to describe patterns in data across time and to fail to detect patterns in known random data needs to be assessed empirically.

A Comparison of Linear and Monotone Multidimensional Scaling Models

David G. Weeks and Peter M. Bentler
University of California, Los Angeles

Multidimensional scaling solutions under the linear and monotone (metric and nonmetric) distance models were compared for several monotone and nonmonotone distortions. Data were generated from random configurations, over a wide range of conditions. Results indicate that, when its assumptions are met, the linear model performs best. When linearity assumptions are not met, the monotone model and the linear model applied to ranked data perform equally well. Recommendations based on these results are offered.

Models for Euclidean multidimensional scaling (MDS) of a single symmetric matrix can be summarized as $h_{ij} = f\{[\Sigma_k(a_{ik} - a_{jk})^2]^{\frac{1}{2}}\}$, where h_{ij} is the observed (dis)similarity between stimuli i and j, and a_{ik} is the projection of stimulus i on dimension k. Although in principle f may be virtually any real valued function, in practice there are two main types. In the linear MDS model, $h_{ij} = bd_{ij} + c$, and the parameter b is an arbitrary scale factor that may be ignored. This linear model is commonly referred to as metric MDS. The monotone model specifies

$$h_{ij} \overset{m}{=} d_{ij},$$

that is, the distances are required only to stand in the same monotone (m) rank order as the dissimilarities. More explicitly, the model requires $d_{ij} \leq d_{kl}$ iff $h_{ij} < h_{kl}$. This monotone model is generally referred to as nonmetric MDS.

This research was supported in part by U.S. Public Health Service Grants MH24149 and DA00017. The University of California, Los Angeles, Office of Academic Computing provided over $2,000 in computer resources required for the simulations and analyses.

We wish to thank J. D. Carroll, E. W. Holman, J. B. Kruskal, F. W. Young, and several anonymous reviewers for helpful comments.

Requests for reprints should be sent to David G. Weeks or Peter M. Bentler, Department of Psychology, University of California, Los Angeles, California 90024.

At this point it may be useful to briefly outline certain aspects of the history of MDS, as this relates to the problems investigated in the current article. The first method for MDS was developed by Torgerson (1952, 1958) and was based on a theorem by Young and Householder (1938). This method solves for the linear model under the Euclidean metric. Nonmetric MDS was introduced by Shepard (1962a, 1962b); this allowed solutions for the monotone model. Kruskal (1964a, 1964b) defined an explicit error function for this model that was minimized by the method of steepest descent. Cooper (1972) developed a method for solving the linear model using a method related to that used by Kruskal, and Bentler and Weeks (1978) developed restricted, hypothesis-testing methods for the linear model. Since its introduction in 1962, the monotone model has come to dominate the field.

The continued use of the monotone model would imply that its superiority over the linear model had been established. Although it has been shown that the monotone model works quite well (e.g., Shepard, 1962b), the superiority of the monotone model over the linear model remains undemonstrated. This point can be made clearer by an examination of a classic study in the field. Ekman (1954) obtained similarity ratings of 14 spectral colors. These ratings were linearly transformed to a 0–1 scale. Then, on the assumption that these values were equivalent to

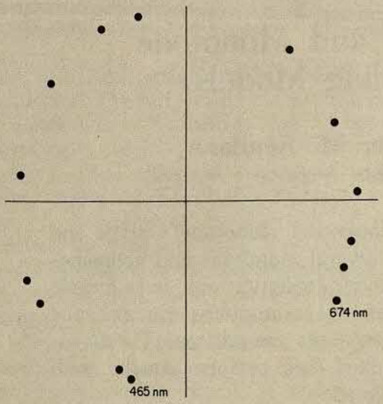

Figure 1. Ekman (1954) color data analyzed by the linear model. (The stimuli were colored lights from 434 nm [violet] to 674 nm [red].)

cosines or correlations between vectors representing the stimuli, the configuration was obtained by a relatively primitive type of factor analysis. The resulting solution was five color clusters in five factors. Shepard (1962b) reanalyzed these data under the monotone MDS model with his new method. He obtained a solution in two dimensions, resembling the color circle. Although Shepard's solution was clearly more appropriate than Ekman's, it was not compared with the linear distance model. Consequently, Shepard's solution does not verify the superiority of the monotone model over the linear model. Indeed, our own reanalysis of the Ekman data under the linear model (see Figure 1) revealed a solution indistinguishable from Shepard's monotone solution.

One would expect the monotone model to be dramatically superior only when the data are substantially nonlinear, but it is possible that most data typically used for MDS are approximately linear on distances. Furthermore, large deviations from "monotonicity" would also tend to be the largest deviations from linearity. "Clearly the success of such an undertaking [mapping a proximity matrix into Euclidean space] depends upon the selection of the proper distance function; that is, the function that will transform the proximity measures into Euclidean distances" (Shepard, 1962a, p. 127). Shepard (1962b) gave several examples of analyses of distances distorted by nonlinear monotone functions. In all cases his method recovered the true configuration, as well as the shape of the distorting function. However, these results were not compared with solutions under the linear model, so that it is not possible to conclude that monotone MDS was markedly superior to linear MDS. It is our purpose in this article to compare results under the linear and monotone models and to explore the robustness of the linear model. We are concerned only with the limited problem of comparing the linear and monotone models in Euclidean exploratory multidimensional scaling; no attention is paid the other important problems (such as how to handle missing data, analysis of non-Euclidean metrics, parameter-constrained scaling methods, transformation of initial solutions to aid interpretation, scaling individual-difference data, the value of alternative nonlinear optimization methods, the relative merit of alternative initial starting configurations, methods for avoiding or evaluating local minima, etc.) that have no relevance to this comparison.

The Problem of Comparison

Attempting to compare metric and nonmetric MDS presents certain serious problems. Results of the comparison should be useful in applied situations, and for that purpose, analysis of real data is advised. In applied situations, however, it may not be possible to determine which solution is "best." In some cases, one solution may make more sense than another, but this is by no means assured (this, of course, presumes that a difference will be found). In many cases, the data might be nearly linear on the true distances and would thus provide no test of the power of nonmetric MDS. Generating distances from a known configuration, and distorting them by a known monotone function, seems more promising. However, the problems of comparison do not end there by any means. Stress, Kruskal's (1964a, 1964b) measure of poorness of fit, is inadequate for the present purpose because it means something different in either case. In the linear model, every deviation from linearity contributes to

stress; in the monotone model, only deviations from monotonicity are counted. The same solution—provided it does not give perfect fit—has to have a higher stress value if stress is measured in terms of linear rather than monotone regression.

It must be acknowledged that certain important determinants of the quality of an MDS solution are not amenable to Monte Carlo, computer simulation techniques. In particular, an acceptable solution is one that makes sense in terms of the particular stimulus domain. Such judgments are usually subjective, often necessarily so. Criteria are also idiosyncratic to the particular data situation. Nonetheless, there is an important component of the quality of a solution that is amenable to quantification and hence to Monte Carlo techniques: the nearness of the estimated parameters to the true parameters of the model. For the sake of simplicity, we consider only the elements of the projection matrix as parameters. The problem reduces to one of finding a measure to characterize the discrepancy between an obtained and a true configuration. The squared correlation between the distances generated by the two configurations is an appropriate measure. In a distance model, differences in orientation and location of the origin are irrelevant, because distances are invariant under such transformations. Usually central dilation is irrelevant, affecting only the scale of the distances. The correlation coefficient is, of course, scale invariant. The correlation of distances is natural in the sense that the error-free component of an observation used in MDS is a distance. The squared correlation has been used before in similar applications (Girard & Cliff, 1976; MacCallum & Cornelius, 1977; Rabinowitz, 1976; Sherman, 1972; Young, 1970). A viable alternative would be a measure of association between two matrices, as developed by Lingoes and Schönemann (1974; Schönemann & Carroll, 1970). We prefer the squared correlation in this case, because it is simpler in both calculation and interpretation (the proportion of variance of one set of distances accounted for by the other). Of course, it must be recognized that since the distances within a set are not independent, standard statistical sampling theory is not relevant to understanding the squared correlation in this context.

A critical problem in MDS is determination of the correct dimensionality (Shepard, 1974). Probably the most common method now in use involves extracting only as many dimensions as can reasonably be interpreted. This method, of course, is not amenable to Monte Carlo studies. A promising objective method involves matching obtained stress curves with those previously obtained by Monte Carlo techniques (e.g., Spence & Graef, 1974; Wagenaar & Padmos, 1971). Unfortunately, these studies employed only the monotone model, and thus their results cannot be used to compare the monotone model with the linear model.

A Simulation Study

Method

Conditions were chosen to cover the range of conditions found in most applications of MDS. Three levels of number of points ($m = 10$, 20, or 30) and four levels of true dimensionality ($t = 1$, 2, 3, or 4) were completely crossed. Elements of the configuration matrices were obtained from a uniform pseudorandom number generator with a range of 1.4, 1.2, 1.0, or .8 for the first through fourth dimensions, respectively. Within each m,t combination there were two independent replications.

Data were obtained by generating true distances from the configuration and by adding random error to the distances. For cases in which this led to negative values, a constant was added such that the smallest value was zero. These values were then transformed by several known functions to produce the sets of data that were analyzed. Error was drawn from a normal distribution with a mean of zero and variances, expressed as proportions of the variance of the true distances, of .25, .75, and 2.0. (The generator used was routine GGNRF [*IMSL Library*, 1975].) Five distorting functions were chosen. The first, $h_{ij} = d_{ij} + e_{ij}$, where h is the data, consisted of no distortion—a linear relationship between data and distances. This was in a sense a control condition by which the severity of the other distortions could be judged. Two distortions, $h_{ij} = (d_{ij} + e_{ij})^4$ and $h_{ij} = (d_{ij} + e_{ij})^{\frac{1}{4}}$, were intended to exemplify severe, monotone distortions. The fourth distortion, $h_{ij} = \text{rank}\ (d_{ij} + e_{ij})$, was particularly important for two reasons: First, the ranked data contain only that information used by the monotone model; second, this condition can always be obtained in real situations by ranking the data, since $\text{rank}\ [f(d + e)] = \text{rank}\ (d + e)$, where f is monotone. The last distortion was $h_{ij} = |d_{ij} + e_{ij} - w|$,

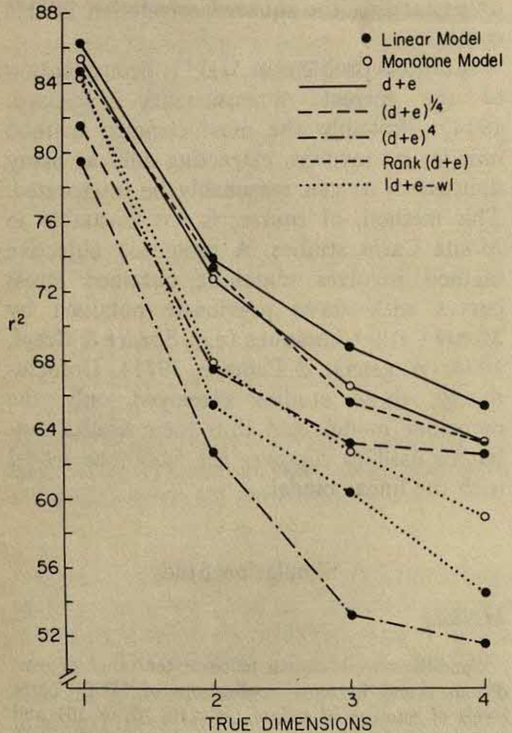

Figure 2. Effect of model, distortions, and number of dimensions on the squared correlation (r^2); $d =$ distance; $e =$ error; $w =$ a constant.

where w is the 20th percentile of $d + e$. This distortion was included more for curiosity than for practical value. We wished to gain some insight into the behavior of the two models when monotonicity was violated.

Thus, 3 (number of points) × 4 (dimensions) × 2 (replications) × 3 (levels of error) × 5 (distortions) = 360 sets of data that were generated. All sets of data were analyzed under the linear model. Under the monotone model, the various monotone distortions have no differential impact. Therefore, only data produced by the linear function and the nonmonotone function were analyzed under the monotone model. (Actually, we performed complete analyses for a small subset of the conditions and confirmed that this was true in practice as well as in theory.) All analyses were done with the KYST program (Kruskal, Young, & Seery, 1973), which uses Kruskal's (1964a, 1964b) method. Starting configurations were obtained by Torgerson's (1958) method. Stress 1, with the primary approach to ties, was specified. Solutions were obtained in from one to six dimensions, but the obtained dimensionality was not allowed to exceed the true dimensionality plus three. This resulted in 10,584 solutions. For each solution, stress and the squared correlation between true and recovered distances were recorded.

Results

Of primary interest were differences in recovery of the true distances between the linear and monotone models. The mean squared correlation for the seven distortion-model conditions, for the cases in which recovered dimensionality equaled true dimensionality, is plotted in Figure 2. (All correlations were positive.) The linear model, with no distortion, was best overall. The rank condition with the linear model and the no-distortion condition with the monotone model were virtually identical and were nearly as good as the first condition. The two other monotone distortions with the linear model were clearly worse than the monotone analysis of ranked data, with which they should properly be compared. For the nonmonotone distortion, the monotone model was superior to the linear model except in the one-dimensional condition.

The effects of error, dimensions, and the number of points on the squared correlation are shown in Figure 3. Again, these data are

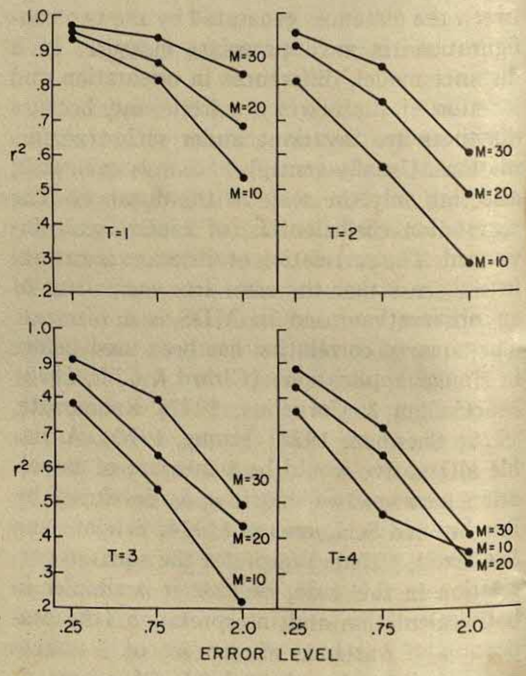

Figure 3. Effect of error, number of points, and number of dimensions on the squared correlation (r^2); T corresponds to true dimensionality; $M =$ number of points.

for recovery in the true dimensionality of the configuration. The squared correlation decreases as error and number of dimensions increase and increases with the number of points. The effects of number of points and number of dimensions reflect the degree of overdetermination of parameters. There were no systematic interactions of error with type of analysis.

The effects of the various factors were examined for the data in which the dimensionality was overestimated or underestimated by one. There were no coherent patterns of results in these data that were different from the data displayed in Figures 2 and 3. Therefore, detailed summaries of these data are omitted.

Discussion

Two aspects of the monotone multidimensional scaling model can be conceptually distinguished. The first is that only the ordinal properties of the data are retained, and the second is that a best fitting monotone function is derived. The results of the present study strongly indicate that only the first aspect has any real practical importance. The ordinal constraints among a matrix of distances are strong enough to determine a highly metric solution (Kruskal & Shepard, 1974; Shepard, 1966, 1974; Young, 1970), and this is true whether the function relating data to recovered distances is linear or monotone. The virtual identity in the squared correlation between the linear, rank conditions and the monotone, no-distortion conditions bears this out. Further, since the squared correlation values in the linear, no-distortion conditions were only slightly higher than either the ranked, linear conditions or the monotone conditions, it seems that the actual interval properties of the data add little over the ordinal constraints.

The other aspect of the monotone model, the function derived from monotone regression, has a serious drawback not shared by the linear model. It is well-known that a problem arises when there are clusters of points such that the within-cluster distances are all smaller than the between-clusters distances. Use of the monotone model can then lead to degenerate solutions, in which the clusters collapse into single points (Shepard, 1974). This can happen because monotonicity is preserved when all small distances are set to zero and all larger distances are set equal to one another. The linear model is not similarly susceptible to degeneracy, because monotone equating of distances creates deviations from linearity, which add to the size of the loss function. Consequently, the rank version of the linear model (rank-linear model) should also be able to avoid such degenerate solutions.

The generally outstanding performance of the rank-linear model is not particularly surprising when one considers that the use of ranks involves using more information from the original data in the rank-linear model than from the original data in the monotone model. In the rank-linear model, the ranks represent a certain distance function for the data; in the monotone model, the distance function is recovered subject only to the weaker constraint that $d_{ij} \leq d_{kl}$ iff $h_{ij} < h_{kl}$. Thus the rank-linear model operates in a data metric analogous to Spearman's rank-order correlation coefficient, whereas the monotone model operates in a data metric analogous to Kendall's tau. In the closely related area of monotone principal-components analysis (e.g., Kruskal & Shepard, 1974), the use of ranked data similarly yields excellent results at a large savings in cost (Woodward & Overall, 1976).

Based on our results, the known problems with monotone regression, and cost considerations, one may wish to approach multidimensional scaling analyses in the following way. First, the scaling is performed under the linear model with no transformation of data. If there are no systematic monotone biases, the solution should be optimal as well as inexpensive. A scatterplot of data to recovered distances must be examined; if systematic nonlinearities are present, the data should be ranked and reanalyzed with the linear model. If no appreciable clustering of points is detected, a monotone scaling would be a suitable (but more expensive) alternative to the second analysis. This approach to

MDS is not appropriate when there is a nonmonotone relation between data and distances. Nonmonotone functions are in general not one to one, they do not necessarily have inverses, and an adequate recovery of the function is not possible. If severe nonmonotonicities exist in the data, it would be neither appropriate nor profitable to employ any distance model. If one were employed, however, the monotone model would seem to be a reasonable choice. It was more robust than the linear model to violations of monotonicity, at least in our data.

In conclusion, the monotone model has the advantage of robustness over the linear model, since, in this study, it performed better than the linear model for all systematic monotone and nonmonotone distortions. The linear model, on the other hand, has the advantage of conceptual simplicity and greater computational efficiency and avoids the danger of degeneracy. The rank-linear model appears to offer the advantages of both. The only computation it requires over the linear model is an initial ranking of data. The ranking eliminates all systematic monotone nonlinearities, whereas the linear analysis avoids the potential of degeneracy due to monotone regression.

Comment on Olson: Choosing a Test Statistic in Multivariate Analysis of Variance

James Stevens
University of Cincinnati

This article questions Olson's claim that the Pillai-Bartlett statistic (V) is superior to Wilks's λ (W) and the Hotelling-Lawley trace (T) for general use in multivariate analysis of variance because of much greater robustness against unequal covariance matrices. It is shown by a sampling of studies from the literature that the example Olson used to demonstrate superiority had extreme subgroup variance differences, which occur very infrequently. For subgroup variance differences much more likely to occur, it is shown that the actual Type I error rates for V, T, and W are very similar. For concentrated noncentrality structures with covariance heterogeneity, it is recommended that any of these three statistics be used, since the slight robustness advantage V has is offset by the greater power of T and W in these situations. For diffuse structures, V is the clear choice as test statistic.

Olson (1976) argued recently, based on robustness and power considerations, that of four multivariate test statistics available (Roy's largest root [R], the Hotelling-Lawley trace [T], Wilks's λ[W], and the Pillai-Bartlett trace [V]), V should generally be used. Olson's argument was mainly based on his statement that V is much more robust than are the other three to violations of the homogeneity-of-covariance-matrices assumption in multivariate analysis of variance.

To illustrate the much greater robustness of V, Olson gave the following example from his 1976 article: Consider a three-group experiment with five subjects per group and six dependent variables at nominal $\alpha = .05$. Then if one group is sampled from a population with variances 36 times as great as those of the other groups, the actual Type I error rate for $V = .09$; but the error rate is .49 for W, .58 for T, and .62 for R. This result does show V to be dramatically more robust than T, W, or R. However, a representative sampling of Olson's (1973) dissertation results indicates that V is only dramatically more robust for extreme subgroup variance differences, as in the above example. Table 1, which presents the sampling of actual Type I error rates from Olson's dissertation for nominal $\alpha = .10$ and .05, shows that for smaller subgroup variance differences the differences in error rates for V, T, and W are very small. The differences in error rates for T, W, and V for nominal $\alpha = .10$ are less than 2%; for W versus V, they are less than about 1%. The differences in error rates for T, W, and V for the more extreme nominal value of .05 are essentially the same. In general, they are very small ($\leq$ 2.3% for T vs. V and $\leq$ 1.5% for W vs. V).

Eight of the nine cases in Table 1 in which the differences in error rates are larger (marked with superscript b) for both nominal values correspond to very large subgroup variance differences on all variables (36I, that is, the population variances of all variables in one group are 36 times greater than the variances of those variables in the remaining groups). For nominal $\alpha = .10$, the actual error rates are at least twice the nominal value. For nominal $\alpha = .05$, the actual error rates are at least three times the nominal value. Therefore, under 36I the error rates for all statistics are far from the nominal value, although relatively speaking V is much more robust.

10	6	10	C(36)	135	84	130	92	129	91	136	73

[a] D = extent of subgroup variance differences: 4I means population variances of all variables in one group are four times greater than the variances of those variables in the remaining groups; C refers to concentrated differences. Thus, C(4) means the population variance on only one variable in one group is four times greater than the variance of that variable in the remaining groups.
[b] Cases in which the differences in error rates for T versus V are greater than 2.5% and for W versus V are greater than 1.5%.

[a] Groups are four levels of parent's education.
[b] Groups are four instructional sets.
[c] Groups are men classified according to degree of obesity.
[d] Groups formed on the basis of two types of contextual organization.
[e] Dependent variables are the amount of dental calculus on six anterior mandibular teeth.

Since V is only much more robust for extreme subgroup variance differences, the following question arises: "How often can one expect to find subgroup variances that differ by a magnitude of 36 to 1?" Table 2 presents the subgroup variances for a small sampling of studies from the literature. Although the sampling is small, it includes nine different sources and considers a variety of criterion variables (achievement, personality, biochemical, and dental). The first point these studies demonstrate is that subgroup variance differences near 36 to 1 occur very infrequently. Only in the Finn (1974) example are there differences of this magnitude, and even there the large differences are confined to certain variables and are not of the I type. The second point these studies illustrate is that the I type of heteroscedasticity Olson considered (in which one group has large variances on all variables and all other groups have equal and smaller variances) is one that probably does not occur very often in practice. Rather, the groups differ in a variety of ways. For example, in the French, Brownell, Graziano, and Hartup (1977) and Smith, Gnanadesikan, and Hughes (1962) studies the largest variances for the three variables in each case fell in three different groups. In Meichenbaum's (1975) study, although the self-instruction group had the largest variances on all three variables, the variances of the variables in the other two groups were far from equal.

To further document that extreme subgroup variance differences (especially of the 36I type) occur rarely in educational and psychological research, a check was made of three major journals: *American Educational Research Journal* for 1972–1977 and *Journal of Educational Psychology* and *Psychological Reports* for 1975–1977. This more extensive sampling confirmed the results of the smaller sampling reported in Table 2.

A secondary part of Olson's argument concerned the power of the four statistics. Which is most powerful depends on how the null hypothesis is false. With a concentrated noncentrality structure, the power ordering (from most to least powerful) is R, T, W, and V. With a diffuse structure (the groups differing along several dimensions), the power ordering is reversed (V, W, T, and R), and power differences among V, W, and T are typically small (Olson, 1973, p. 73).

Therefore, if assumptions are met, the choice of test statistic depends on the degree of concentration of the noncentrality structure. If assumptions are not met, then I would argue as follows: For concentrated or nearly concentrated structures, use V, W, or T as the test statistic, because the discrepancies in actual Type I error for these three, for subgroup variance differences likely to occur in practice, are so small that which of the statistics is used makes no practical difference. Although V will generally be slightly more robust, the gain in power obtained by using T or W instead of V will offset or more than offset V's slight robustness advantage. There is evidence to suggest that concentrated structures are quite prevalent in psychological research (Bock, 1975, p. 154). For diffuse structures, however, it must be acknowedged that V is the preferred choice, since in these cases it is slightly more robust and somewhat more powerful.

Confirmatory Inference and Geometric Models

Lawrence J. Hubert
Department of Education
University of California, Santa Barbara

Michael J. Subkoviak
University of Wisconsin—Madison

A confirmatory technique is discussed that is appropriate for comparing a given geometric model with supplementary data available on the same objects used in the representation. The inference procedure is based on relatively straightforward distribution-free principles and requires the comparison of one proximity matrix, possibly reconstructed from a particular geometric model, with a second structure matrix obtained from the supplementary information. Two examples are presented that illustrate the generality of the same statistical approach.

In the literature on data analysis over the last 20 years, a distinction between exploratory and confirmatory procedures has become very popular (Hildebrand, Laing, & Rosenthal, 1977; Kaiser, 1970; Tukey, 1962). An exploratory strategy typically involves the use of an analysis technique on a given data set with the aim of identifying interesting relationships, patterns, and the like. Alternatively, a confirmatory approach requires the test of an a priori conjecture that is generated from a source distinct from the data to be used for the purposes of validation. This latter test in the present context is correlational, and thus the term *confirmation* is given a limited meaning that does not imply the absolute correctness of a hypothesis. Since a correlational analysis can never exclude all competing explanations, we argue when it is justified that the pattern of data is not unrelated to the conjectured pattern.

It may be obvious that confirmatory analyses would be desirable adjuncts to many of the current exploratory methods used in the study of proximity matrices (such as clustering and multidimensional scaling), but very few techniques have been proposed that could help carry out such a program with any degree of rigor. Users of the newer data reduction procedures lack confirmatory techniques even of a correlational nature and must rely on intuitive arguments based on whatever additional information is available for the objects being studied. Although this practice is commendable given the current state of the art, it is now possible to proceed one step further using the correlational methods presented in this article and incorporate the same information relevant to a post hoc explanation more directly in a confirmatory manner. To provide a complete illustration and also to limit the scope of the discussion, our emphasis is on geometric models, or more generally, on data representations that can be given some type of explicit geometric interpretation. In short, the sections to follow illustrate how confirmatory data analysis problems that are phrased geometrically can be approached through a relatively straightforward concept of correlation. Depending on the context, it is conceivable that the method presented here might be used in conjunction with a geometric model; in extending an existing analysis strategy based on geometric notions; as a means of interpreting a given model with respect to supplementary information; or finally, as a preliminary to the construction of a desired geometric representation. The first example

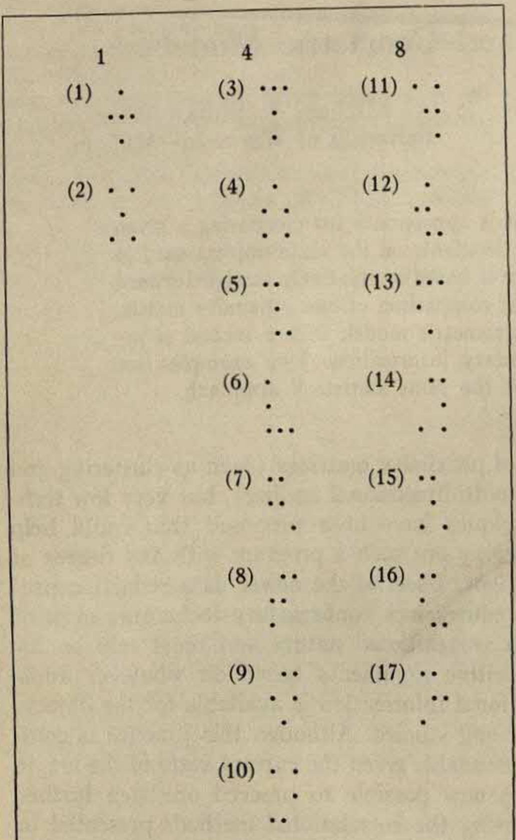

Figure 1. Patterns used by Glushko (1975) in testing Garner's (1962) pattern goodness hypothesis; each pattern is characterized by one of three inferred equivalence class sizes: 1 and 2 by a size of one, 3–10 by a size of four, and 11–17 by a size of eight. Glushko's patterns were as wide as they were high.

below formalizes the basic ideas that are presented here.

Example 1: Figural Goodness

In a recent study concerned with the "goodness" of patterns, Glushko (1975) attempted to verify Garner's (1962) basic hypothesis regarding what makes one pattern better than another. To be more specific, each of the 17 patterns used by Glushko, listed in Figure 1, can be characterized by the size of an inferred equivalence class. The term *equivalence* is used to label the set of patterns that contain a single figure plus all other configurations that result from reflections or from 90° rigid rotations. As indicated in Figure 1, 2 of the Glushko patterns construct the same configuration under all of these operations, 8 patterns have four associated figures, and finally, 7 patterns produce 8 different members. According to Garner, the subjective judgment of pattern goodness is a direct function of the size of a configuration's inferred equivalence class, with the smaller size classes corresponding to the better patterns.

To test Garner's hypothesis using the 17 patterns of Figure 1, Glushko first obtained a symmetric measure of proximity between each pair of patterns by using a choice task. All 136 different pattern combinations were presented to 20 subjects, who were asked to indicate their preference. These choices were then summed over subjects and subtracted from an expected preference frequency of 10. Due to the subtraction of 10, the absolute values of these differences, given in the lower triangular portion of Table 1, form a symmetric measure of proximity defined for all pattern pairs and provide data in a form that can be subjected to a variety of data reduction techniques. In particular, Glushko attempted to represent the structure of the proximity function by first placing the 17 configurations in a two-dimensional space using Shepard and Kruskal's multidimensional scaling routine (see Kruskal, 1964a, 1964b). Given this geometric representation, Johnson's (1967) diameter clustering results were then superimposed, producing a representation similar to that we give in Figure 2 (here, we only indicate the clustering result defined by three subclasses). Clearly, one strong dimension (the vertical) can be identified as that of equivalence class size. In addition, the clusters themselves correspond fairly well to a grouping on the basis of the same criterion except for the minor misplacement of the two configurations numbered 10 and 11.

The process of verifying Garner's hypothesis through a multidimensional scaling and clustering might be considered rather circuitous, especially since the equivalence class hypothesis implies a definite structure for the original proximity measure. Although one dimension is very strong in this example and the clustering and scaling results are clear-cut, unambiguous outcomes of this type are

[a] Symmetric proximity matrix is in lower triangle; structure matrix is in upper triangle.

somewhat rare. In general, when a strong hypothesis is not reflected as dramatically in the scaling or clustering results, it may be difficult to decide whether the hypothesis is inadequate or whether the data reduction techniques are at fault. In the typical application, the researcher may be able to identify portions of his or her theory in a scaling or clustering solution, but may lack a strategy for measuring in any precise manner the actual degree of confirmation or nonconfirmation.

As an alternative approach, it should be possible to test directly whether the pattern goodness hypothesis is reflected in the original proximities and bypass the scaling and clustering solutions altogether. To introduce some notation, suppose the patterns are denoted by $o_1, o_2, \ldots, o_n$ (where $n = 17$ in our example). Furthermore, let $q(o_i,o_j)$ refer to the symmetric[1] proximity between patterns o_i and o_j, and let **Q** refer to an organization of these measures into a 17×17 square matrix with rows and columns labeled by the objects or patterns $o_1, o_2, \ldots, o_n$. By convention, the diagonal of **Q** is assumed to consist entirely of zeros. In addition to the empirical proximity matrix **Q**, the stated hypothesis is represented numerically by a second "structure" matrix **C** with elements $c(o_i,o_j)$. Explicitly, suppose $N(o_i)$ denotes the size of the inferred equivalence class for object o_i, and let f be some monotone function on the integers, for example, $f(x) > f(y)$ if and only if $x > y$. Then as a formal definition, $c(o_i,o_j) = f[|N(o_i) - N(o_j)|]$, where it is assumed that $c(o_i,o_j) = 0$ for $o_i = o_j$. Although many functions can be used and the actual choice depends on the researcher's judgment as to the most appropriate relative size of the structure values, for the purposes of an illustration f is taken as the identity, that is, $f(x) = x$. In other words, the symmetric function values $c(o_i,o_j)$, given in the upper triangular portion of Table 1, are merely the absolute values of the differences in equivalence class sizes associated with the objects o_i and o_j.

As an operational interpretation, the theory used to generate the function $c(o_i,o_j)$ is given empirical support if the two sets of elements, $c(o_i,o_j)$ and $q(o_i,o_j)$, have a similar patterning of high and low entries. Although many formal indices for this relationship can be defined, the pairing of a proximity $q(o_i,o_j)$ with a structure value $c(o_i,o_j)$ suggests that the

[1] Extensions to asymmetric measures are possible using the generalizations discussed in Hubert and Schultz (1976).

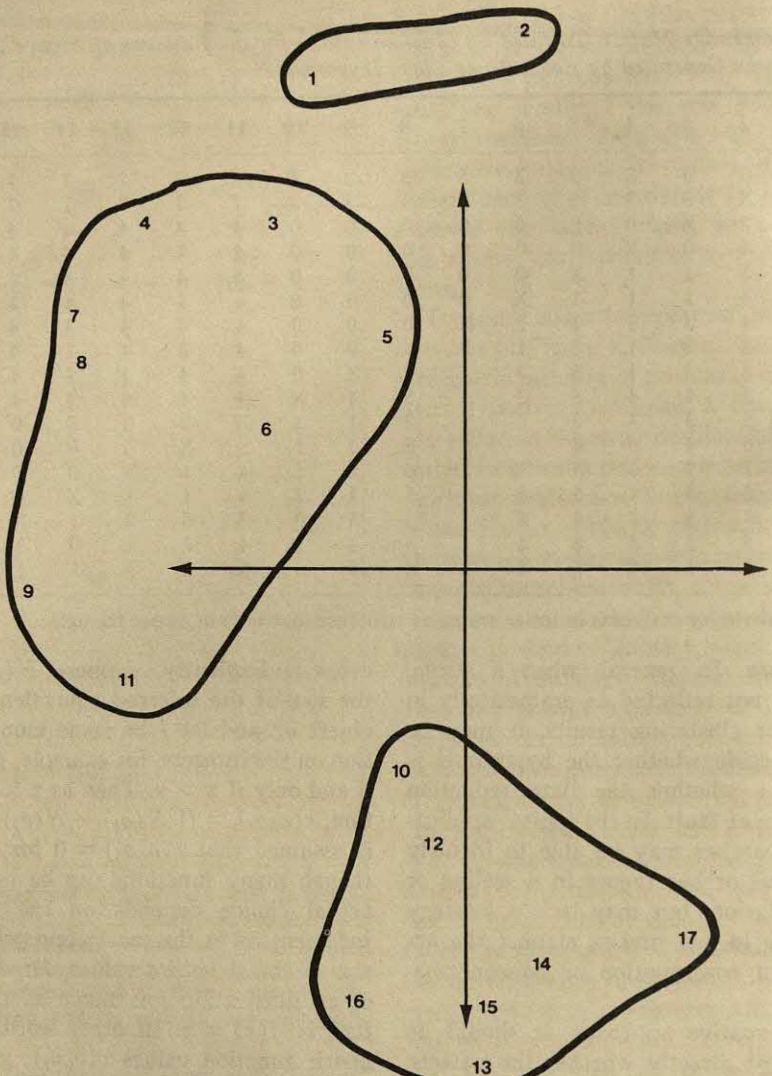

Figure 2. Two-dimensional scaling of the 17 Glushko (1975) patterns.

simple Pearson product-moment correlation may be a reasonable measure to consider; it is thus our major choice for the sequel.[2] Once this index is calculated, the next problem concerns its significance and, specifically, whether the size of the observed correlation between the values for $q(o_i,o_j)$ and $c(o_i,o_j)$ is sufficient to reject some appropriately defined null hypothesis.

To generate a reasonable reference distribution for the observed correlation, suppose one assumes a randomness hypothesis that can hopefully be rejected. More specifically, it is conjectured that the partition of the objects (or patterns) $o_1, o_2, \ldots, o_n$ occurred randomly or was chosen at random from the set of all

[2] Since the conditional assumption of fixed functions $c(o_i,o_j)$ and $q(o_i,o_j)$ is made, several other indices are formally equivalent to the Pearson statistic, at least from an inference point of view. For instance, either the raw sum of cross-products, $\Sigma_{i,j}\ c(o_i,o_j)q(o_i,o_j)$, or the sum of squared differences, $\Sigma_{i,j}\ [c(o_i,o_j) - q(o_i,o_j)]^2$, could be used. Alternatively, a transformation on the original function values could be carried out and the comparison performed on the transformed values. Thus, if the ranks of $c(o_i,o_j)$ and $q(o_i,o_j)$ are used, then Spearman's rank correlation index is the measure of correspondence.

partitions of the same form. In our case, the conjectured partition contains three classes with two, eight, and seven objects in each, and thus, the null hypothesis of interest asserts that this particular partition occurred randomly and consequently does not reflect the patterning of entries in the proximity matrix Q. Moreover, any such partition of Q of the same form (i.e., number of classes) will produce a correlation index and when completely enumerated will generate an exact reference distribution for the null hypothesis. Since it is assumed that the partition is conjectured prior to observing the data, the hypothesis of randomness is an active candidate to consider, and its rejection is not a foregone conclusion.

From an inference perspective, the observed correlation for the conjectured partition can be compared with the distribution generated by complete enumeration, and if the observed correlation is at a suitably extreme percentage point, the null hypothesis of randomness can be rejected. Moreover, when the correlation actually obtained for the conjectured partition is large enough, this index can be assumed to reflect a value that was obtained nonrandomly; that is, at least to some extent, the functions $q(o_i,o_j)$ and $c(o_i,o_j)$ have a common patterning of high and low entries. In short, a permutation (or randomization) test of the type discussed in detail by Bradley (1968), Edgington (1969), or Lehmann (1975) is applied. For instance, if the functions $q(o_i,o_j)$ and $c(o_i,o_j)$ are specialized appropriately (Hubert & Baker, 1977), then this same strategy includes the usual randomization analysis of a one-way design.

Although complete enumeration is generally prohibitive because of computational costs and although an exact reference distribution is thus typically too expensive to obtain, Monte Carlo approximations are relatively inexpensive (cf. Hubert & Schultz, 1976; Schultz & Hubert, 1976). For instance, Table 2 presents the frequency results of selecting 1,000 partitions of the desired form at random and with replacement and should provide an approximate distribution that is fairly accurate for this application. In particular, using the Figure 1 data, the observed correlation for the Garner (1962) hypothesis is .64, which

Table 2
Approximate Distribution for Comparison of Structure and Proximity Matrices in Table 1

Note. $N = 1{,}000$.

is greater than any value observed in the Table 2 distribution. Thus, the null hypothesis of a random partition can be rejected at an approximate significance level of, say, .001, suggesting that the equivalence class hypothesis is supported by the patterning of the proximity values.

Using the previous example as a guide, the salient features of a confirmatory analysis should be evident. Given the proximity measure $q(o_i,o_j)$ and some conjecture specified in terms of a structure function $c(o_i,o_j)$, the observed correlation between $q(o_i,o_j)$ *and* $c(o_i,o_j)$ is compared with a reference distribution generated under a hypothesis of randomness. If the obtained correlation is at an extreme percentage point, the correspondence between $q(o_i,o_j)$ and $c(o_i,o_j)$ is declared significant, with the added implication that the conjecture leading to the construction of $c(o_i,o_j)$ may help explain some of the variation present in the empirical proximity measures.[3] As

[3] If different functions $c(o_i,o_j)$ are used on the same data set, our confirmatory strategy (as well as any other) could turn out to be an exploratory analysis. In this case, however, the difficulty of multiple significance testing arises.

usual, the size of the correlation can be considered an index of the degree of correspondence or confirmation.

Although the example given above implies that a randomness hypothesis should be defined in terms of selecting a partition of a given form at random, a more general hypothesis that will generate exactly the same distribution can also be considered. Explicitly, if the values assigned by the proximity function are organized, as before, into an $n \times n$ square matrix $\mathbf{Q}$ and, similarly, the values of the structure function into a second $n \times n$ square matrix, $\mathbf{C}$, both with rows and columns labeled as $o_1, o_2, \ldots, o_n$, then each reordering of the rows and simultaneously of the corresponding columns of $\mathbf{Q}$ in relation to the fixed $\mathbf{C}$ matrix will induce a specific partition of the n objects $o_1, \ldots, o_n$. In other words, for our $\mathbf{C}$ matrix of Table 1, any reordering of $\mathbf{Q}$ produces a partition defined by subsets containing two, eight, and seven objects. The first two rows and columns of the reordered $\mathbf{Q}$ matrix define the objects in the class of size two, the next eight rows and columns define a class of eight objects, and the remaining seven rows and columns define the last object class of size seven. Morover, if a reordering of $\mathbf{Q}$ is chosen at random, that is, if all $n!$ possible reorderings are considered equally likely, then this assumption induces a random selection of a partition of the same general form used in the original construction of the $\mathbf{C}$ matrix. In short, the random reordering of $\mathbf{Q}$ and the random selection of a partition will generate exactly the same distribution of correlations, and thus, either concept can be used in producing an approximate reference table through Monte Carlo simulation. This generalization will prove important when a confirmatory approach is necessary but cannot be identified by a specific partitioning of an object set.

Although we suggest carrying out a confirmatory test through the use of an approximate distribution obtained through Monte Carlo simulation, it is also possible to find the exact mean and variance of the complete reference distribution by formulas, given only the matrices $\mathbf{C}$ and $\mathbf{Q}$. Specifically, the mean of the Pearson correlation r is zero, and its variance is equal to

$$V(r) = [1/\tbinom{n}{2}]\left\{1 + \frac{1}{(n-2)G_2H_2} \times \left[2(G_1 - G_2)(H_1 - H_2) + \frac{(2G_1 - G_2)(2H_1 - H_2)}{(n-3)}\right]\right\},$$

where

$$G_1 = \sum_i \{\sum_{\substack{j \\ i \neq j}} [q(o_i,o_j) - \bar{q}]\}^2;$$

$$G_2 = \sum_i \sum_{\substack{j \\ i \neq j}} [q(o_i,o_j) - \bar{q}]^2;$$

$$H_1 = \sum_i \{\sum_{\substack{j \\ i \neq j}} [c(o_i,o_j) - \bar{c}]\}^2;$$

$$H_2 = \sum_i \sum_{\substack{j \\ i \neq j}} [c(o_i,o_j) - \bar{c}]^2;$$

$$\bar{q} = \frac{2}{n(n-1)} \sum_{i<j}\sum q(o_i,o_j);$$

$$\bar{c} = \frac{2}{n(n-1)} \sum_{i<j}\sum c(o_i,o_j).$$

As an example of how the variance calculation can be used for the data of Figure 1 and the structure function of Table 1, we find $[V(r)]^{\frac{1}{2}} = .0879$. Converting to a Z score for the observed correlation of .641, a value of 7.28 is obtained, which would indicate a rather significant result if it were possible to assume even a crude normality (see Mantel, 1967, for the appropriate moment derivations).[4]

Although the Pearson product-moment correlation is used as a measure of correspondence between $c(o_i,o_j)$ and $q(o_i,o_j)$, it is not legitimate to test the index using the usual

[4] Unfortunately, since the few normal convergence theorems that are available are also very specialized, little general information is available on the adequacy of a normal approximation. Several Monte Carlo studies, however, suggest that normality may provide an adequate approximation in some applications (e.g., Schultz & Hubert, 1976). Thus, until more complete information is available, it may be more appropriate to rely on random sampling from the complete permutation distribution or to use the exact moments to obtain a conservative significance level, as discussed in Hubert and Levin (1976a).

formulas presented in most elementary tests. In particular, the permutation procedure discussed above preserves the internal linkages among the function values $c(o_i,o_j)$ and $q(o_i,o_j)$, whereas an application of even the usual permutation test on a correlation, as discussed in Bradley (1968), does not. In the latter case, all $\binom{n}{2}!$ reorderings of one set of function values would be considered equally likely and would be compared with some fixed ordering of the second set of $\binom{n}{2}$ function values. Thus, dependencies among the function values would be destroyed and a different variance of $1/[\binom{n}{2} - 1]$ for r would result. These same comments apply to the use of the well-known parametric hypothesis test of no correlation based on the t distribution.

Example 2: Multidimensional Scaling Applications

Geometric configurations that are generated as a result of a multidimensional scaling (Carroll & Chang, 1970; Kruskal, 1964a, 1964b) represent another context in which the confirmatory paradigm could be used to test a priori conjectures. To give an illustration, consider the application of Carroll and Chang's individual differences scaling procedure to data collected by Wish, Deutsch, and Biener (1970). The objects of study for this analysis were 12 nations, and each of 18 subjects rated the proximity of all pairs of nations on a 9-point scale (large numbers indicated a greater degree of similarity). The resulting 18 proximity matrices, all of size 12×12, can be analyzed by the Carroll–Chang procedure. The group result selected for our discussion is a two-dimensional configuration, shown in Figure 3, in which each nation is represented by a point and in which the interpoint distances reflect the degree of similarity between the corresponding nations as judged by the group; for example, the distance between the United States and China is large, since they are perceived on the average as being very dissimilar. (It should be noted at the outset that two separate two-way analyses are performed below, and the interlocking

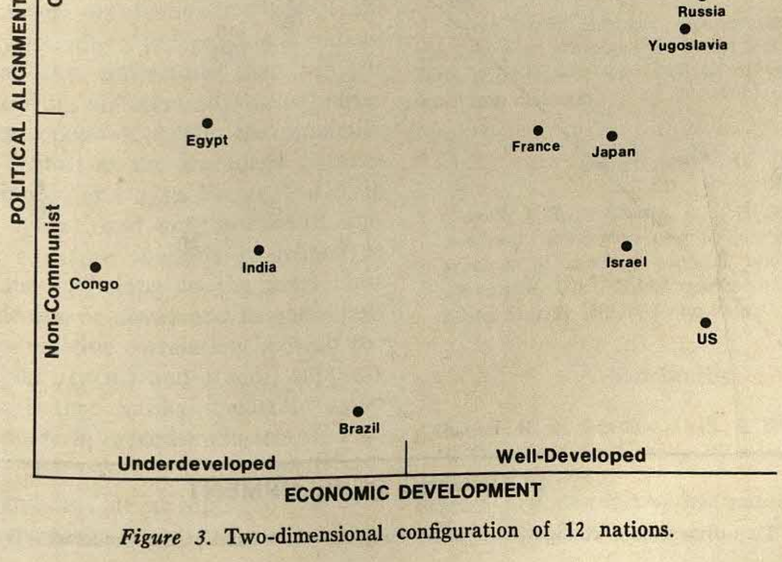

Figure 3. Two-dimensional configuration of 12 nations.

weights between what are called the group and subject spaces are not considered.)

Instead of attempting to label and interpret dimensions per se, suppose the researcher wishes to test the a priori hypothesis that an outside variable, such as political alignment, may account in part for the distances between nations. In other words, the researcher is interested in confirming the conjecture that nations close together subscribe to similar political philosophies and, conversely, that those far apart have different political systems. In this case the proximity function $q(o_i,o_j)$ would merely refer to the distance between nations o_i and o_j in Figure 3.

The structure function $c(o_i,o_j)$ would be obtained from the outside variable of political alignment. For instance, if political alignment were simply dichotomized as communist versus noncommunist, then $c(o_i,o_j)$ might be defined as zero if o_i and o_j were both communist or both noncommunist and as one otherwise. With this notation, a large positive correlation between $q(o_i,o_j)$ and $c(o_i,o_j)$ would indicate that nations of similar political persuasion were located close together in Figure 3. As it turns out, the observed correlation between the interpoint distances in Figure 3 and the dichotomous variable of political alignment is .50, which is significant at, say, the .001 level (approximately) when referred to the distribution of correlations for 1,000 random reorderings of matrix Q. In short, there is statistical support for the hy-

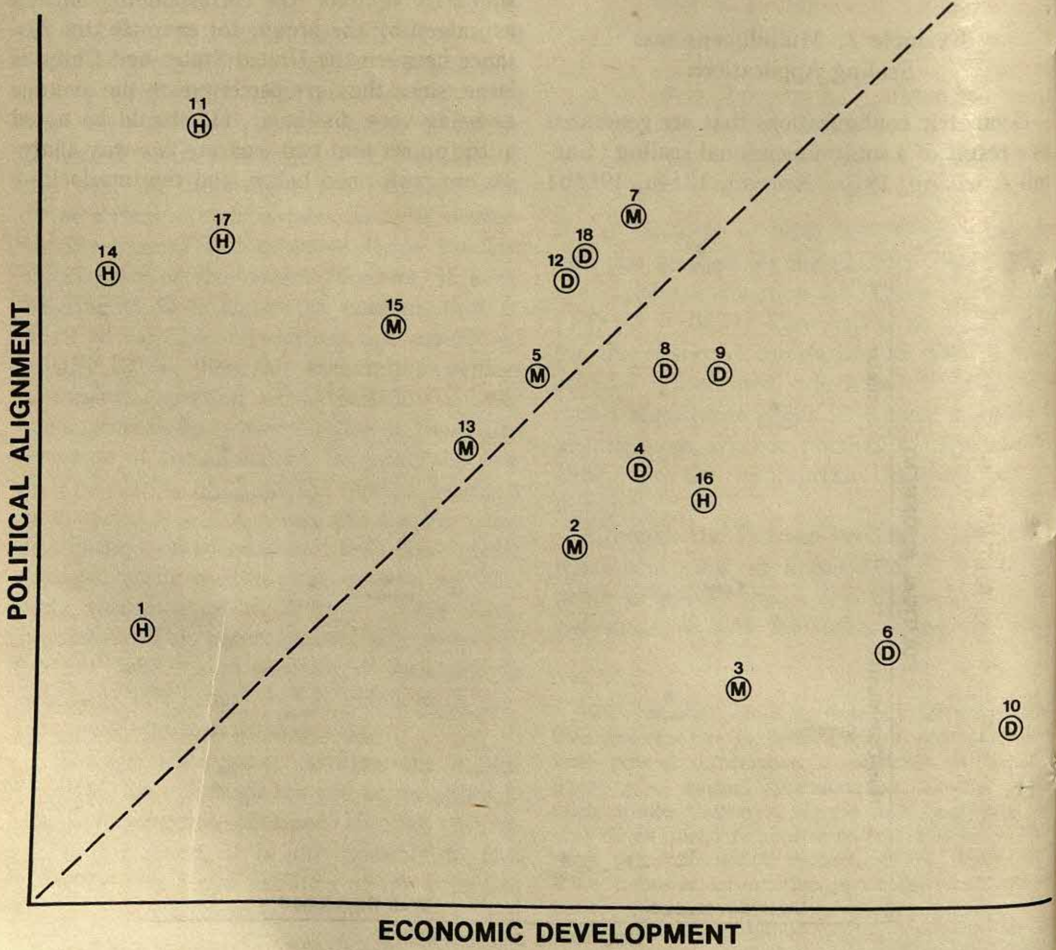

Figure 4. Two-dimensional configuration of 18 subjects. (H = hawk; M = moderate; D = dove.)

pothesis that the information provided by the variable of political alignment (or some closely related variable) is reflected in the arrangement of points. The question regarding other possible competing hypotheses, however, is unanswered.

In addition to the geometric configuration of nations given in Figure 3, the Carroll–Chang procedure also produces a configuration of the particular subjects that supplied the similarity data, as shown in Figure 4. The horizontal and vertical axes of Figure 4 are exactly the same as those of Figure 3, representing economic development and political alignment, respectively. Numerical coordinates (w_{i1}, w_{i2}) again locate a subject o_i in Figure 3 and, furthermore, indicate how much emphasis subject o_i gives to political alignment and economic development when rating the similarities of nations. Thus, subject 10 gives primary emphasis to the economic development dimension, subject 11 gives primary emphasis to political alignment, and subjects in the center of the configuration weight both dimensions about equally.

As indicated in Figure 4, Wish et al. further classified each subject either as a hawk (H), a moderate (M), or a dove (D) according to the person's stance on the Vietnam War and descriptively argued that subjects in the same class tend to weight the two dimensions similarly. Since it is hypothesized that hawks, moderates, and doves will form reasonably homogeneous clusters in Figure 4, the confirmatory paradigm can provide a statistical test for the conjecture that subjects weight dimensions differentially according to their political opinions. Again, the proximity function is defined as the Euclidean distance between points o_i and o_j in Figure 4 (i.e., in the subject space), and for the sake of simplicity, the structure function is defined as zero if o_i and o_j belong to the same class (hawk, moderate, or dove) and as one otherwise. A large positive correlation between the function values $q(o_i,o_j)$ and $c(o_i,o_j)$ supports the conjecture that hawks, moderates, and doves tend to form separate clusters in Figure 4. Since the observed correlation is .19, which is significant at an approximate .009 level, the hypothesis is given statistical support. Wish et al. noted specifically that hawks tend to cluster above the diagonal in Figure 4 and give relatively more emphasis to the political alignment factor, whereas moderates and doves cluster below the diagonal and give relatively more weight to economic development.[5]

Discussion

As should be evident in the examples given above, the confirmatory approach developed in this article has a number of applications that are related to the use and development of geometric models, either those that occur naturally or those derived from some intermediate data reduction process. In addition to the illustrations provided, a number of other correspondences to the methodological literature of the behavioral sciences could be developed that the reader may be interested in pursuing further; see, for example, Schultz and Hubert (1976), Hubert and Baker (1977), Hubert and Levin (1976a, 1976b), Hubert and Schultz (1976), Hubert (1978), Carroll and Chang (Note 1), Althauser, Burdick, and Winsborough (1966), Campbell, Kruskal, and Wallace (1966), Cliff & Ord (1973), Geary (1954), Mielke, Berry, and Johnson (1976), Royaltey, Astrachan, and Sokal (1975), and Winsborough, Quarantelli, and Yutzy (1963).

---

[5] Since strong algebraic dependencies exist among the interpoint distances, it is not legitimate to perform a simple one-way analysis of variance on the Euclidean distances.

Nonparametric Large-Sample Pairwise Comparisons

Kenneth J. Levy
State University of New York at Buffalo

Tukey's procedure for making pairwise comparisons among means is discussed within the context of three nonparametric models. Examples are presented in which Tukey's procedure, in accord with Hartley's results, is employed to make comparisons associated with a Kruskal-Wallis one-way analysis of variance test for ranked data, Friedman's two-way analysis of variance test for ranked data, and Cochran's test of change for dichotomous data.

Marascuilo and McSweeney (1967) discussed methods for testing post hoc hypotheses concerning trends associated with the Kruskal–Wallis (1952) one-way analysis of variance (ANOVA) test for ranked data, the Friedman (1937) two-way ANOVA test for ranked data, and the Cochran (1950) test of change for dichotomous data.

Within the framework of these three nonparametric tests, an investigator might be primarily interested in testing hypotheses associated with the set of all possible pairwise comparisons that arise from the k treatments associated with each of these three nonparametric test procedures. The purpose of the present article is to illustrate the application of a Tukey-type procedure for controlling the joint significance level associated with such comparisons. Marascuilo and McSweeney's general multiple comparison approach could be employed in the present context if an investigator were only interested in making pairwise comparisons; however, the present procedure produces more powerful tests because the set of pairwise comparisons is only a subset of the set of all possible comparisons for which Marascuilo and McSweeney's approach is most applicable.

The Kruskal–Wallis Test

Following Marascuilo and McSweeney (1967), consider k independent samples, each of size n, drawn from k continuous probability distributions. Let $N = nk$ and let the original observations be replaced by ranks $(1, 2, \ldots, N)$ in accord with the Kruskal–Wallis test. Let $R_1, R_2, \ldots, R_k$ be the rank sums of each of the samples, and let $\bar{R}_1, \bar{R}_2, \ldots, \bar{R}_k$ be the respective average ranks.

From Marascuilo and McSweeney, when $E(\bar{R}_1) = E(\bar{R}_2) = \cdots = E(\bar{R}_k)$, where $E(\ )$ is the expected value operator, it should be noted that if n is sufficiently large, the $\bar{R}_j$ will be approximately multivariate normal with

$$E(\bar{R}_j) = \frac{(N+1)}{2},$$

$$\operatorname{var}(\bar{R}_j) = \sigma_j^2 = \frac{(N+1)(N-n)}{12n},$$

and

$$\operatorname{cov}(\bar{R}_j, \bar{R}_{j'}) = \sigma_{jj'} = \frac{-(N+1)}{12}$$

$$= \sigma_j^2\left[\frac{-n}{(N-n)}\right].$$

Consider the following result from Hartley (1950). If $\mathbf{y}' = (y_1, y_2, \ldots, y_k)$ is a multivariate normal vector with zero means and dispersion $\sigma^2\mathbf{B}$ (where $\mathbf{B}$ is a square matrix whose diagonal elements equal a and whose off-diagonal elements equal b for some a and b), then the range of the y_js is distributed as the range of k independent and identically distributed normal variates with zero means and variances $\sigma^2(a-b)$. In the present context, in accord with Hartley's result, the range of the $\bar{R}_j$s is distributed as the range of k in-

dependent and identically distributed normal variates with zero means and variances $\sigma^2(a-b)$, where $\sigma^2(a-b) = N(N+1)/12n$. So

$$P\{(\bar{R}_{\max} - \bar{R}_{\min}) \le q_{\alpha,k,\infty}[N(N+1)/12n]^{\frac{1}{2}}\} = 1 - \alpha,$$

where $\bar{R}_{\max} - \bar{R}_{\min}$ is the range of the $\bar{R}_j$s and $q_{\alpha,k,\infty}$ is the upper α point of the studentized range with infinite degrees of freedom. From this probability statement follows the usual Tukey result that the probability is $1-\alpha$ that all of the $(1/2)k(k-1)$ pairwise differences $[E(\bar{R}_j) - E(\bar{R}_{j'})]$ simultaneously satisfy

$$(\bar{R}_j - \bar{R}_{j'}) - \omega q_{\alpha,k,\infty} \le [E(\bar{R}_j) - E(\bar{R}_{j'})] \le (\bar{R}_j - \bar{R}_{j'}) + \omega q_{\alpha,k,\infty},$$

where $\omega = [N(N+1)/12n]^{\frac{1}{2}}$.

For data involving r sets of tied observations, let t_s be the number of tied observations in set s. Kruskal and Wallis (1952) suggested that for any group of t_s tied observations, the tied ranks could be replaced by their mean. From Dunn (1964, p. 249), when $E(\bar{R}_1) = E(\bar{R}_2) = \cdots = E(\bar{R}_k)$, it can be demonstrated that if n is sufficiently large, the $\bar{R}_j$ will be approximately multivariate normal with

$$E(\bar{R}_j) = \frac{(N+1)}{2},$$

$$\operatorname{var}(\bar{R}_j) = \left[\frac{N(N+1)}{12} - \frac{\sum_{s=1}^{r}(t_s^3 - t_s)}{12(N-1)}\right] \times \left(\frac{N-n}{nN}\right),$$

and

$$\operatorname{cov}(\bar{R}_j, \bar{R}_{j'}) = \left(\frac{-n}{N-n}\right)\operatorname{var}(\bar{R}_j).$$

Thus, in accord with Hartley's result, when ties occur in the data, the range of the $\bar{R}_j$s is distributed as the range of k independent and identically distributed normal variates with zero means and variances:

$$(\omega^*)^2 = \left(\frac{N}{N-n}\right)\operatorname{var}(\bar{R}_j).$$

Therefore, for tied data, it follows that the probability is $1-\alpha$ that all possible pairwise comparisons $[E(\bar{R}_j) - E(\bar{R}_{j'})]$ simultaneously satisfy

$$(\bar{R}_j - \bar{R}_{j'}) - \omega^* q_{\alpha,k,\infty} \le [E(\bar{R}_j) - E(\bar{R}_{j'})] \le (\bar{R}_j - \bar{R}_{j'}) + \omega^* q_{\alpha,k,\infty},$$

where

$$\omega^* = \left[\frac{N(N+1)}{12n} - \frac{\sum_{s=1}^{r}(t_s^3 - t_s)}{12n(N-1)}\right]^{\frac{1}{2}}.$$

A Kruskal–Wallis-Type Example

Consider the example discussed in Marascuilo and McSweeney (1967, p. 404). This example may also be found in Hays (1973, p. 684). The hypothetical example involves noise intensity as a treatment variable with six levels. The dependent variable is a subject's score obtained in a complex performance task under one of the noise intensity levels. The data for this example appear in Table 1.

An investigator wishes to test the 15 different hypotheses associated with pairwise comparisons of the form $[E(\bar{R}_j) - E(\bar{R}_{j'})] = 0$. Since there are $r = 19$ sets of tied observations, ω^* should be calculated. For these data, $\omega^* = 5.52$. If the joint significance level of the 15 tests is to be controlled at $\alpha = .05$, one also needs to obtain the value of $q_{.05,6,\infty}$. This value may be found in many statistical texts; and $q_{.05,6,\infty} = 4.03$. Those comparisons for which

$$|\bar{R}_j - \bar{R}_{j'}| > \omega^* q_{\alpha,k,\infty}$$

should be declared significant. In the present example, $\omega^* q_{\alpha,k,\infty} = 22.25$, and

$\lvert\bar{R}_1-\bar{R}_2\rvert = 17.75$	$\lvert\bar{R}_2-\bar{R}_3\rvert = 7.05$	$\lvert\bar{R}_3-\bar{R}_5\rvert = 33.00^*$
$\lvert\bar{R}_1-\bar{R}_3\rvert = 24.80^*$	$\lvert\bar{R}_2-\bar{R}_4\rvert = 8.70$	$\lvert\bar{R}_3-\bar{R}_6\rvert = 43.00^*$
$\lvert\bar{R}_1-\bar{R}_4\rvert = 9.05$	$\lvert\bar{R}_2-\bar{R}_5\rvert = 25.95^*$	$\lvert\bar{R}_4-\bar{R}_5\rvert = 17.25$
$\lvert\bar{R}_1-\bar{R}_5\rvert = 8.20$	$\lvert\bar{R}_2-\bar{R}_6\rvert = 35.95^*$	$\lvert\bar{R}_4-\bar{R}_6\rvert = 27.25^*$
$\lvert\bar{R}_1-\bar{R}_6\rvert = 18.20$	$\lvert\bar{R}_3-\bar{R}_4\rvert = 15.75$	$\lvert\bar{R}_5-\bar{R}_6\rvert = 10.00.$

Thus, 6 out of the 15 comparisons should be declared significant; these 6 significant comparisons are designated with asterisks.

Friedman's Test

Following Marascuilo and McSweeney (1967), consider n individuals or matched groups observed in a repeated measures design in which each subject or group is tested under

Table 1
Data for the Kruskal–Wallis-Type Example

Noise intensity level					
1	2	3	4	5	6
18 (10.5)	34 (40.5)	39 (49.5)	37 (44.5)	15 (8)	14 (7)
24 (20.5)	36 (43)	41 (51)	32 (34.5)	18 (10.5)	19 (12.5)
20 (14.5)	39 (49.5)	35 (42)	25 (22.5)	27 (25.5)	5 (1)
26 (24)	43 (54.5)	48 (58.5)	28 (28)	22 (17)	25 (22.5)
23 (18.5)	48 (58.5)	44 (56)	29 (30.5)	28 (28)	7 (2)
29 (30.5)	28 (28)	38 (47)	31 (33)	24 (20.5)	13 (5.5)
27 (25.5)	30 (32)	42 (52.5)	34 (40.5)	21 (16)	10 (3)
33 (37.5)	33 (37.5)	47 (57)	38 (47)	19 (12.5)	16 (9)
32 (34.5)	37 (44.5)	53 (60)	43 (54.5)	13 (5.5)	20 (14.5)
38 (47)	42 (52.5)	33 (37.5)	23 (18.5)	33 (37.5)	11 (4)

Note. Numbers in parentheses are the ranks associated with the original dependent variable scores.

k conditions. Let the original observations for each subject be replaced by ranks $(1, 2, \ldots, k)$ in accord with Friedman's two-way ANOVA procedure. Let $R_1, R_2, \ldots, R_k$ be the rank sums of each of the conditions, and let $\bar{R}_1, \bar{R}_2, \ldots, \bar{R}_k$ be the respective average ranks.

From Marascuilo and McSweeney, when $E(\bar{R}_1) = E(\bar{R}_2) = \cdots = E(\bar{R}_k)$, it should be noted that if n is sufficiently large, the $\bar{R}_j$ will be approximately multivariate normal with

$$E(\bar{R}_j) = \frac{(k+1)}{2},$$

$$\text{var}\,(\bar{R}_j) = \sigma_j^2 = \frac{(k+1)(k-1)}{12n},$$

and

$$\text{cov}\,(\bar{R}_j, \bar{R}_{j'}) = \sigma_{jj'} = \frac{-(k+1)}{12n}$$

$$= \sigma_j^2\left[\frac{-1}{(k-1)}\right].$$

From Hartley's (1950) result follows the usual Tukey result that the probability is $1 - \alpha$ that all of the pairwise differences $[E(\bar{R}_j) - E(\bar{R}_{j'})]$ simultaneously satisfy

$$(\bar{R}_j - \bar{R}_{j'}) - \omega q_{\alpha,k,\infty} \leq [E(\bar{R}_j) - E(\bar{R}_{j'})] \leq (\bar{R}_j - \bar{R}_{j'}) + \omega q_{\alpha,k,\infty},$$

where $\omega = [k(k+1)/12n]^{\frac{1}{2}}$.

For data involving r sets of tied observations in which tied ranks are placed by their mean, it can be demonstrated that when $E(\bar{R}_1) = E(\bar{R}_2) = \cdots = E(\bar{R}_k)$, the $\bar{R}_j$ will be approximately multivariate normal if n is sufficiently large, with

$$E(\bar{R}_j) = \frac{(k+1)}{2},$$

$$\text{var}\,(\bar{R}_j) = \left(\frac{k-1}{nk}\right)\left[\frac{k(k+1)}{12} - \frac{\sum_{s=1}^{r}(t_s^3 - t_s)}{12n(k-1)}\right],$$

and

$$\text{cov}\,(\bar{R}_j, \bar{R}_{j'}) = \frac{-1}{(k-1)}\,\text{var}\,(\bar{R}_j).$$

Thus, for tied data, in accord with Hartley's result, it follows that the probability is $1 - \alpha$ that all possible pairwise comparisons $[E(\bar{R}_j) - E(\bar{R}_{j'})]$ simultaneously satisfy

$$(\bar{R}_j - \bar{R}_{j'}) - \omega^* q_{\alpha,k,\infty} \leq [E(\bar{R}_j) - E(\bar{R}_{j'})] \leq (\bar{R}_j - \bar{R}_{j'}) + \omega^* q_{\alpha,k,\infty},$$

where

$$\omega^* = \left[\frac{k(k+1)}{12n} - \frac{\sum_{s=1}^{r}(t_s^3 - t_s)}{12n^2(k-1)}\right]^{\frac{1}{2}}.$$

A Friedman-Type Example

Consider an example discussed in Hays (1973, p. 785). This hypothetical example involves a treatment variable with four levels. The treatments are applied to 11 groups of

Table 2
Data for the Friedman-Type Example

	Treatment level			
Group	1	2	3	4
1	1 (2)	4 (3)	8 (4)	0 (1)
2	2 (2)	3 (3)	13 (4)	1 (1)
3	10 (3)	0 (1)	11 (4)	3 (2)
4	12 (3)	11 (2)	13 (4)	10 (1)
5	1 (2)	3 (3)	10 (4)	0 (1)
6	10 (3)	3 (1)	11 (4)	9 (2)
7	4 (1)	12 (4)	10 (2)	11 (3)
8	10 (4)	4 (2)	5 (3)	3 (1)
9	10 (4)	4 (2)	9 (3)	3 (1)
10	14 (4)	4 (2)	7 (3)	2 (1)
11	3 (2)	2 (1)	4 (3)	13 (4)

Note. Numbers in parentheses are the ranks associated with the original dependent variable scores.

four matched subjects. The data for this example appear in Table 2.

An investigator wishes to test the six different hypotheses associated with pairwise comparisons of the form $[E(\bar{R}_j) - E(\bar{R}_{j'})] = 0$. Since there are no ties within any rows of the original data, ω should be calculated. For these data, $\omega = .39$. If the joint significance level of the six tests is to be controlled at $\alpha = .05$, one needs to obtain the value of $q_{.05,4,\infty}$; this value is 3.63. Those comparisons for which

$$|\bar{R}_j - \bar{R}_{j'}| > \omega q_{\alpha,k,\infty}$$

should be declared significant. In the present example, $\omega q_{\alpha,k,\infty} = 1.42$, and

$$|\bar{R}_1 - \bar{R}_2| = .55 \quad |\bar{R}_2 - \bar{R}_3| = 1.27$$
$$|\bar{R}_1 - \bar{R}_3| = .72 \quad |\bar{R}_2 - \bar{R}_4| = .54$$
$$|\bar{R}_1 - \bar{R}_4| = 1.09 \quad |\bar{R}_3 - \bar{R}_4| = 1.81^*.$$

Thus, only one out of the six comparisons should be declared significant; this comparison is designated with an asterisk.

Cochran's Test

Following Marascuilo and McSweeney (1967), consider n individuals observed in a repeated measures design in which each subject is tested under k conditions. In this case, the observations are dichotomous, for instance, *success* and *failure*. Let S_i be the number of successes for the ith subject. Let $T_1, T_2, \ldots, T_k$ be the sums for each condition, and let $\bar{T}_1, \bar{T}_2, \ldots, \bar{T}_k$ be the respective averages.

From Marascuilo and McSweeney, when $E(\bar{T}_1) = E(\bar{T}_2) = \cdots = E(\bar{T}_k)$, it should be noted that if n is sufficiently large, the $\bar{T}_j$ will be approximately multivariate normal with

$$E(\bar{T}_j) = \frac{\sum_{i=1}^{n} S_i}{nk},$$

$$\text{var}(\bar{T}_j) = \sigma_j^2 = \frac{1}{n^2} \sum_{i=1}^{n} \frac{S_i}{k}\left(1 - \frac{S_i}{k}\right),$$

and

$$\text{cov}(\bar{T}_j, \bar{T}_{j'}) = \sigma_{jj'} = \frac{-1}{(k-1)}\sigma_j^2.$$

From Hartley's (1950) result follows the usual Tukey result that the probability is $1 - \alpha$ that all of the pairwise differences $[E(\bar{T}_j) - E(\bar{T}_{j'})]$ simultaneously satisfy

$$(\bar{T}_j - \bar{T}_{j'}) - \omega q_{\alpha,k,\infty} \leq [E(\bar{T}_j) - E(\bar{T}_{j'})] \leq (\bar{T}_j - \bar{T}_{j'}) + \omega q_{\alpha,k,\infty},$$

where

$$\omega = \left\{\left[\frac{k}{(k-1)n^2}\right] \sum_{i=1}^{n} \frac{S_i}{k}\left(1 - \frac{S_i}{k}\right)\right\}^{\frac{1}{2}}.$$

Table 3
Data for the Cochran-Type Example

	Problem			
Subject	1	2	3	4
1	1	1	1	0
2	0	1	1	1
3	0	0	1	0
4	1	1	1	1
5	0	1	0	0
6	0	0	1	0
7	1	0	0	0
8	0	0	1	1
9	0	0	0	0
10	1	0	0	0
11	1	0	1	0
12	0	0	1	1
13	0	1	0	1
14	1	0	0	0
15	0	1	0	0
16	1	0	1	1
17	0	1	0	0
18	0	0	1	0
19	0	1	1	0
20	0	0	1	1

A Cochran-Type Example

Consider an example discussed in Hays (1973, p. 774). This hypothetical example involves 20 randomly selected subjects who were each given four problems in a random order. A 1 was recorded for a successful solution and a 0 for a failure. The data for this example appear in Table 3.

An investigator wishes to test the six different hypotheses associated with pairwise comparisons of the form $[E(\bar{T}_j) - E(\bar{T}_{j'})] = 0$. For these data, $\omega = .11$. If the joint significance level of the six tests is to be controlled at $\alpha = .05$, one needs to obtain the value of $q_{.05,4,\infty}$; this value is 3.63. Those comparisons for which

$$|\bar{T}_j - \bar{T}_{j'}| > \omega q_{\alpha,k,\infty}$$

should be declared significant. In the present example, $\omega q_{\alpha,k,\infty} = .40$, and

$$|\bar{T}_1 - \bar{T}_2| = .05 \quad |\bar{T}_2 - \bar{T}_3| = .20$$
$$|\bar{T}_1 - \bar{T}_3| = .25 \quad |\bar{T}_2 - \bar{T}_4| = .05$$
$$|\bar{T}_1 - \bar{T}_4| = .00 \quad |\bar{T}_3 - \bar{T}_4| = .25.$$

Thus, none of the six comparisons should be declared significant.

A Comment Concerning Sample Sizes

The analytic results presented in the present article obtain for large values of n. A further point that should be addressed concerns the question of what constitutes a large sample size for each of the cases considered here. Future empirical results would surely be helpful in answering such questions; however, there appears to be some information presently available that could serve as a useful guide. Siegel (1956) pointed out that the distribution of the usual Kruskal–Wallis test statistic can be closely approximated by an appropriate chi-square distribution when $n > 5$; Hays (1973) pointed out that the distribution of the usual Friedman test statistic can be closely approximated by an appropriate chi-square distribution when $n \geq 10$ and $k \geq 4$; and empirical results reported by Levy and Narula (1976) suggest that the distribution of the usual Cochran test statistic can be closely approximated by an appropriate chi-square distribution when $n \geq 18$. Although further work on these questions is needed, I suggest that the preceding statements provide useful information concerning the minimal values of large sample sizes for each of the cases considered in this article.

Interobserver Agreement, Reliability, and Generalizability of Data Collected in Observational Studies

Sandra K. Mitchell
Department of Maternal and Child Nursing
University of Washington

Research in developmental and educational psychology has come to rely less on conventional psychometric tests and more on records of behavior made by human observers in natural and quasi-natural settings. Three coefficients that purport to reflect the quality of data collected in these observational studies are discussed: the interobserver agreement percentage, the reliability coefficient, and the generalizability coefficient. It is concluded that although high interobserver agreement is desirable in observational studies, high agreement alone is not sufficient to insure the quality of the data that are collected. Evidence of the reliability or generalizability of the data should also be reported. Further advantages of generalizability designs are discussed.

Almost everyone engaged in research recognizes the need for reliable measuring instruments. Reliability is a central topic particularly for courses and textbooks concerned with the behavioral sciences. In spite of varying theoretical derivations, its definition is remarkably uniform: A reliable instrument is one with small errors of measurement, one that shows stability, consistency, and dependability of scores for individuals on the trait, characteristic, or behavior being assessed.

Historically, the study of reliability has been linked to the study of individual differences and has been largely restricted to standardized tests of intelligence, achievement, and personality. These tests, however, are increasingly being replaced in developmental and educational psychology research by observations of subjects made in natural and quasi-natural settings. Although these observational studies vary widely in content and method, they all use human observers to record (and in some cases to summarize and abstract) the behavior of the subjects. Surprisingly, the reliability of these observational methods has not received the same attention as has the reliability of the more traditional methods (Johnson & Bolstad, 1973).

There are at least three different ways to think about the reliability of observational data. First, the researcher could focus on the extent to which two observers, working independently, agree on what behaviors are occurring. A coefficient that reflects the extent of this agreement has often been used to report reliability in observational studies. Second, the observational measure could be considered a special case of standardized psychological test, and the definitions of reliabil-

The preparation of this article was supported in part by Contract NO1-NU-14174 with the Division of Nursing, Bureau of Health Resources and Development, U.S. Public Health Service, Health Resources Administration, Department of Health, Education, and Welfare. The article is based in part on a dissertation submitted in partial fulfillment of the requirements for the PhD degree at the University of Washington.

I would like to thank Halbert B. Robinson and Kathryn E. Barnard for their support of the dissertation research, and Terence R. Mitchell and Nancy E. Jackson for their comments on an earlier draft of the article.

ity that come from classic psychometric theory (e.g., test–retest and alternate forms) could be used. Finally, an observational measure could be thought to provide data that are under the influence of a number of different aspects of the observation situation (e.g., different observers or different occasions), including individual differences among subjects. This third viewpoint was developed in Cronbach's (Cronbach, Gleser, Nanda, & Rajaratnam, 1972) theory of generalizability. The purpose of this article is to examine the appropriateness and correct interpretation of these three coefficients when they are used to reflect the quality and dependability of data gathered in observational studies.

Observer Agreement

To insure that data collected by human observers are objective, researchers typically obtain and report coefficients that demonstrate that two or more observers watching the same behavior at the same time will record the same data. These coefficients are offered as the reliability of the instrument being used.

Interobserver Agreement Percentage

The most common index of the quality of the data collected in observational studies is the interobserver agreement percentage. In its simplest form, this coefficient is just what its name implies: the percentage of time units during which the records of two observers are in agreement about the record of behavior.

Two comments can be made about the use of observer agreement percentages. First, the majority of studies report data only in this fashion. Consider, for example, the field of developmental psychology, in which about one third of recently published research articles use observational techniques. In Volume 47 (1976) of *Child Development*, 33 full-length articles reported observational measures. Of these studies, just under half (49%) reported only observer agreement figures as indicants of the quality of their data. Similarly, of 21 observational studies reported in Volume 12 (1976) of *Developmental Psychology*, 57% reported observer agreement percentages only.

Second, the amount of variability among the subjects in a study has very little impact, at least in theory, on the size of an interobserver agreement percentage. In actual practice, however, the degree of variability can make quite a difference: In very homogenous groups, observer agreement percentages are necessarily quite high because all scores given to all subjects are very close together. Thus, a measure that shows high agreement may, in some populations at least, have done a poor job of differentiating among subjects.

Other Problems With Observer Agreement

The interobserver agreement percentage has several important shortcomings. It is, first of all, insensitive to degrees of agreement, that is, it treats agreement as an all-or-none phenomenon, with no room for partial or incomplete agreement. In this sense, the percentage underestimates the actual extent of agreement between two observers. Second, some agreement between independent observers can be expected on the basis of chance alone. For many observational studies, especially those that use frequency counts of individual behaviors, the extent of this chance agreement is dependent on the rates at which the target behaviors occur. Behaviors with very high and very low frequencies can have extremely high chance levels of agreement (Johnson & Bolstad, 1973). In this sense, the percentage appears to overestimate the real agreement.

These difficulties in the use of observer agreement percentages are not unknown, and considerable effort has been expended to develop indices that overcome them. The alternative coefficients have been reviewed in detail elsewhere (Tinsley & Weiss, 1975). In general, they have been designed to overcome the mathematical shortcomings of the agreement percentage, such as chance levels of agreement.

A serious question remains, however, about the utility of these alternatives. In spite of their mathematical superiority, they deal with only one source of error (observer disagreement), and they deal with it without regard

to the magnitude of the individual differences. These alternatives may give a more accurate picture of the level of observer agreement in a study than does the simple percentage, but they do not otherwise describe the stability, consistency, and dependability of the data that have been collected.

Influences on Observer Agreement

Interobserver agreement has been experimentally studied as a phenomenon in its own right. In these experiments, observer accuracy, that is, agreement with a predetermined correct behavioral record, is the dependent variable.

Reid (1970) compared the accuracy of observers during overt and covert assessment of their reliability and found that they were significantly more accurate when they were aware that they were being checked. Romanczyk, Kent, Diament, and O'Leary (1973) found a similar drop from the overt to the covert assessment situation. They also found that observers recorded behavior differently depending on which of several researchers' records they thought their own records would be compared with. Taplin and Reid (1973) found that observer accuracy decreased between the end of a training period and the beginning of data collection and that it increased on days when "spot checks" were expected. Mash and McElwee (1974) reported that observers who had been trained to code "predictable" behavior (i.e., conversations with redundant information) showed a decline in accuracy when they later coded "unpredictable" behavior, whereas observers trained with unpredictable sequences showed no such decline in accuracy. Taken together, these studies imply that differences in experience, mental set, and training of observers can influence the accuracy with which behavioral records are made and scored.

Interobserver agreement has also been used as the dependent variable in studies that compare different methods of observation. McDowell (1973) found comparable observer agreement in time sampling and continuous recording of infant caretaking activities in an institution. Lytton (1973) found the interobserver agreement of ratings, home observations, and laboratory experiments to vary only slightly, but the amounts of time and effort necessary to achieve these levels were quite different. Mash and McElwee's (1974) rating system with only four categories was used more accurately than was an eight-category form. It appears, then, that there are differences in the interobserver agreement that can be expected from different methods of behavioral observation. These differences are reflected both in different levels of agreement for equal amounts of training and inequal levels of agreement for different amounts of training.

It is difficult, however, to put these agreement differences into perspective without knowledge of the overall variability among subjects in the studies. If between-subjects variability is low, then the reported differences in agreement due to observer instructions or observational methods may considerably influence the outcome of the study. If between-subjects variability is high, on the other hand, then these differences will probably have little influence. The studies that used agreement as a dependent variable have identified some problem areas in data collection, but they have not evaluated the relative importance of these problems.

Psychometric Theory of Reliability

The classical method of determining the reliability of a test is for the researcher to obtain two scores for a group of subjects on the test. These two scores may come from two separate scorings of the instrument, from administration of two parts or forms of the instrument to the subjects, or from two administrations of the same instrument to the subjects. The correlation between the two scores is the reliability of the instrument.

The central theoretical concept that underlies this psychometric view of reliability is that every test score is composed of two parts: a *true score,* which reflects the presence or extent of some trait, characteristic, or behavior, plus an *error score,* which is random and independent of the true score (Nunnally, 1967). The proportion of variance accounted

for by each of these parts is estimated from the correlation between the two scores obtained on the instrument.

The variance attributable to individual differences is usually given the same interpretation, regardless of how the two scores used to compute it were obtained. It reflects stable differences among individuals—the true score part of the data. The variance that is attributable to measurement error, however, is subject to varying interpretations, depending on how the two scores were obtained.

The error always includes, of course, the real error—those random fluctuations of the myriad factors that may affect the behavior being measured. These include such variables as the health or mental state of the subjects, the lighting or temperature in the testing room, and so forth. But the error also includes other sources of variation, depending on the method used to obtain the two scores. These other sources include differences within and between scorers, differences between different sections or forms of a test, and changes in subjects' behavior between two administrations of a test.

Thus, the three most common procedures for determining reliability involve (a) obtaining two separate scorings of the same instrument (intrascorer or interscorer reliability), (b) obtaining scores on two parts of the same instrument or on two very similar instruments (split-half or alternate-forms reliability), and (c) obtaining two scores from two separate administrations of the same instrument (test–retest reliability).

The researcher who wishes to use one of these classical methods of determining reliability in an observational study must somehow make his or her observations fit into the same general pattern as psychological tests. However, instead of one test with many items, all intended to measure the same trait, characteristic, or behavior, the observational researcher has a tool with a relatively small number of categories, with each category intended to measure a different trait, characteristic, or behavior. For each of these categories, which are generally mutually exclusive, data are usually collected during many distinct time units.

The most satisfactory way of making such data fit into the classic pattern seems to be to consider each mutually exclusive category (or type of behavior) a separate test with its own reliability. Each time unit is considered to be an item, since all time units are intended to measure the same trait, behavior, or characteristic. For example, a behavioral code might record a child's proximity to the teacher during each 10-sec unit of an observation. Each 10-sec unit would be an item in a test that measured proximity. If the measure consisted of a single summary score (such as in a rating), then there would be, in effect, no individual items at all, just one score.

This analogy between test reliability and the reliability of observational data can be extended to apply to each of the traditional ways of obtaining scores: intrascorer or interscorer reliability, split-half or alternate-forms reliability, and test–retest reliability.

Intrascorer or Interscorer Reliability

A clinical psychologist interested in self-directed aggression might listen twice to tape recordings of patients' responses to a projective test, each time counting the number of self-destructive statements. The correlation between the two counts for the group of patients would be the intrascorer reliability of the self-destructiveness score. The true score implied by this correlation would reflect real differences in self-destructiveness among the patients. The error would include not only the random error but also any inconsistencies in the psychologist's use of the self-destructiveness scale.

In actual practice, it is more likely that two psychologists would listen to the tape recordings. The correlation between their separate counts would be an interscorer reliability coefficient. The true score would again reflect real differences, but the error would reflect differences between the psychologists in their use of the scale, along with random error.

A similar situation exists, of course, when two or more observers record the behavior of subjects in other natural and quasi-natural settings. The correlation between the scores of two observers who kept track of how much

individual attention each child received from the teacher would be an interobserver reliability coefficient. This coefficient, once again, should not be confused with the observer agreement percentage.

Split-Half or Alternate-Forms Reliability

One way of determining the reliability of a standardized test is to compare scores on two subdivisions of the test (odd- and even-numbered items, frequently) or scores on two very similar versions of the test. In an observational study, the corresponding comparisons would be between subdivisions of one observation (e.g., odd- and even-numbered minutes during a tennis lesson), or between two very similar observations (first and second halves of a lesson, perhaps). This is an example of how time units can be considered analogous to test items.

Just as with interobserver reliability, the true score component of the variance in split-half or alternate-forms reliability reflects consistent individual differences among subjects. The error component, however, has a different interpretation. Along with random fluctuations in the behavior of the subjects, real differences in subject behavior between the two observed subdivisions are included as part of the error.

Test–Retest Reliability

Perhaps the most straightforward way to obtain two scores in a reliability study is to administer the same instrument at two different times. An observer might, for example, visit classrooms on different days to record the teacher's use of a particular instructional technique. As before, the true score is assumed to reflect some stable trait, characteristic, or behavior. In this case, the error includes not only random fluctuations of subject behavior but also whatever real changes in subject behavior have occurred between the two administrations of the test.

It is interesting to note that there is little difference between alternate-forms and test–retest reliability for observational measures. Since time units serve as items, observations made on different days can be considered either as alternate-forms or as test–retest conditions, depending on the situation.

Use of Reliability Coefficients

Three comments apply to all of these versions of the reliability coefficient. First, although the examples given are from hypothetical observational studies, real observational studies do not make use of all of the possible coefficients. Interobserver reliability or agreement is reported to the virtual exclusion of split-half and test–retest coefficients. Once again, developmental psychology can serve as an example. In Volume 47 (1976) of *Child Development*, 49% of the full-length research articles that used observational methods reported only observer agreement, and 39% more reported interobserver correlation coefficients. Only three of the studies (12%) reported a reliability coefficient that reflected the stability of subject behavior over time, that is, a split-half or test–retest reliability. Similarly, in Volume 12 (1976) of *Developmental Psychology*, 57% of the studies reported agreement only, 38% reported observer reliability coefficients, and only one study used a measure based on more than one sample of behavior per subject.

Second, although this discussion has emphasized the sources of error in these coefficients, the variance of true scores is as important in determining the size of the reliability coefficient as the variance of error scores is. Recall that the reliability of a test score can be expressed

$$\frac{\text{true score variance}}{\text{true score variance} + \text{error variance}}.$$

For a given level of error variance, then, an instrument will have a lower reliability when it is used on a homogenous group of subjects (low true score variance) than it will when it is used on a more heterogenous group (high true score variance). For instance, if the error variance is 10 and the true score variance is also 10, the reliability of the instrument is 10/20 or .50. But if the error variance is 10 and the true score variance is 40, the reliability of the instrument is 40/50 or .80. This is

in contrast to the observer agreement percentage, which is highest for homogenous groups of subjects.

Third, it should be repeated that reliability and observer agreement are not the same. It is possible, as illustrated by Tinsley and Weiss (1975), to have high interobserver agreement and a low reliability (correlation) coefficient, and vice versa. For instance, two observers might have perfect agreement about the color of shoes worn by children in a classroom, but if all the children wore red shoes, shoe color would not differentiate among the children. On the other hand, there might be a high correlation between two observers' records of the duration of a teacher's attention to a particular youngster, but if one observer's watch ran slower than the other's watch, they would probably never agree on the actual duration of the attention.

The differences between agreement and reliability are based on the way the two indices are defined. Reliability coefficients partition the variance of a set of scores into a true score (individual differences) and an error component. The error component may include random fluctuations in the behavior of subjects, inconsistencies in the use of the scale, differences among observers, and so forth. Interobserver agreement percentages, on the other hand, carry no information at all about individual differences among subjects and contain information about only one of the possible sources of error—differences among observers. In other words, a reliability coefficient reflects the relative magnitude of all error with respect to true score variability, whereas an agreement percentage reflects the absolute magnitude of just one kind of error.

All in all, there is no perfect reliability coefficient, nor is there one that is even generally best. Coefficients that use two scorings of the same instrument (interobserver and intraobserver reliability) confound random subject error with differences within and between scorers. Coefficients that use scores from subdivisions or alternative forms of the instruments (split-half and alternate-forms reliability) confound random subject error with differences between the subdivisions or forms. Finally, coefficients that use scores from the same instrument administered on two occasions (test–retest reliability) confound measurement errors with real changes in subject behavior that occur between the two administrations. The methods described cannot, then, separately estimate variance in test scores attributable to scorers, subtests (or forms), or occasions, nor can they consider these sources of error simultaneously. A more inclusive, multivariate theory is needed.

Generalizability Theory

Cronbach and his associates (Cronbach et al., 1972) have developed a theory that they call the theory of *generalizability*. (For a brief introduction to the theory, see J. P. Campbell, 1976, pp. 185–222.) Instead of assuming, as does classical test theory, that individual differences constitute the only lawful source of variation in test scores, generalizability theory assumes that there may be a number of sources of variation. These sources of variation other than individual differences are called *facets*. Different scorers, alternate test forms, or administration on different occasions are examples of facets that might be studied. A particular combination of facets makes up the *universe* to which test scores may be generalized.

A generalizability study (G study) is more reminiscent of a factorial study in experimental psychology than of a reliability study. In a G study, the researcher must collect data by systematically sampling conditions from each facet in the universe. For instance, two scorers might each score two alternate forms of a test given on different days to a group of subjects. Using an analysis of variance, it is then possible to independently estimate the contributions of each of the facets—scorers, forms, occasions, as well as subjects—to the overall variation in the set of test scores. Besides looking at the conventional F statistic to establish whether each facet makes a significant contribution to the scores, it is possible to compute what Cronbach calls *variance components*. These variance components reflect the size rather than the statistical significance of the contribution of each facet to the observed scores.

In examining the quality of observational data, though, not only are the absolute sizes of the variance components of interest but the relative sizes of the components are also important. The relative sizes, therefore, are the focus of this discussion.

Recall that a reliability coefficient reflects the partitioning of variance into true and error components and that the coefficient is the ratio of true score variance to obtained score variance. It represents, in other words, the proportion of the total variance that is accounted for by individual differences. In the same way, generalizability coefficient reflects the partitioning of variance into components that correspond to the facets sampled in the G study. The coefficient itself (an intraclass correlation) combines these components in a ratio that also represents the proportion of variance attributable to individual differences for a particular universe (set of conditions).

It should not be assumed, however, that a G study generates one coefficient that is appropriate for all applications of the instrument. On the contrary, one G study can generate several coefficients, each corresponding to a different universe of conditions. This fact points to an important distinction between the psychometric theory of reliability discussed earlier and the theory of generalizability. In psychometric theory, conditions of testing (or otherwise obtaining data) are assumed to influence only measurement error, not the true score on the instrument. In generalizability theory, on the other hand, the conditions of testing are assumed to influence the score itself. What Cronbach and his colleagues have shown is that while true scores all contain a common component, they also contain additional different components depending on the design; that is, it is not just the error variance that differs among the several reliability coefficients. This relationship can be illustrated by returning to the earlier example of interscorer reliability—two psychologists counting self-destructive statements from tape recordings. In generalizability terms, this is a one-facet study, that is, it samples observations from one facet (in this case, scorers) in addition to observations of different subjects. Analyzed as a G study, one can estimate variance components for subjects, for scorers, and for the interaction of subjects and scorers (which in this case is confounded with the residual error). The generalizability coefficient from this G study would reflect the dependability of a score for a subject generalized over scorers. In other words, it would indicate the proportion of variance accounted for by individual differences in subjects, above and beyond any effects accounted for by differences between scorers.

Suppose that a second facet—occasions—were added to this study, so that each scorer would count self-destructive statements for each tape two times. This study combines aspects of the interscorer and the intrascorer reliability studies. The analysis of this two-facet G study would yield variance components for subjects, for scorers, and for occasions (which in this case would be interpreted as intrascorer change). Further, variance components could be computed for each of the possible interactions of these facets: Subjects × Scorers, Subjects × Occasions, Scorers × Occasions, and Subjects × Scorers × Occasions (which in this case is confounded with residual error). The generalizability coefficient from this study would reflect the proportion of variance accounted for by individual differences in subjects apart from the effects between and within scorers.

Suppose further that this study were extended to three facets by having each psychologist use two different scoring methods for each tape recording he or she listened to (perhaps a count of self-destructive statements and a global rating of self-destructiveness). Observational methods would then be a facet in the universe of generalization.

Clearly each facet that is added to the study makes the information available from the analysis more complete. But there is a significant cost for the extra information provided by each facet: The number of observations required of each subject is multiplied by the number of conditions sampled in the facet. In the present example, the one-facet study would have two scores, the two-facet study would have four scores, and the three-

facet study would have eight scores for each subject.

Described below are some three-facet G studies that parallel the intraobserver–interobserver, split-half, and test–retest reliability studies that were discussed earlier. All of these G studies use the same three facets (observers, observational methods, and occasions) sampled for all subjects. The studies differ in their definitions of *occasions* of measurement and thus in their interpretations of the resulting coefficients. The relationships among the reliability studies and the proposed G studies are summarized in Table 1.

Table 1
Correspondence Between Reliability Studies and Generalizability Studies

Measurement occasions	Reliability study	Generalizability study
Separate scorings of the same behavior or instrument	Intrascorer or interscorer	Duplicate
Scores on two subdivisions of an instrument or behavior sample, or two very similar instruments or behavior samples	Split half or alternate forms	Session
Scores from separate administrations of the same instrument or separate samples of behavior	Test–retest	Developmental

Duplicate Generalizability

One study with this basic design might use audiotaped or videotaped recordings of behavior, which would be scored on more than one occasion by more than one observer, using more than one form of an observational instrument. In this G study (which I call *duplicate generalizability*), the occasions of observation actually consist of exactly the same behavior by the subjects. It is, then, an extension of the traditional intrascorer or interscorer reliability study. A reliability study uses two scores for each subject (usually from two different scorers) and confounds measurement error with differences within and between scorers. A duplicate G study, on the other hand, has many scores for each subject and separately estimates the contribution of differences within and among observers. Although *occasions* is a facet in this G study, variance attributable to occasions cannot be interpreted as within-subject change, since the same behavior occurs on each occasion of observation. In this study, occasions variance should be interpreted as a measure of within-observer stability. A duplicate G study would be appropriate for demonstrating the dependability of an instrument used in a study in which the stability of the behavior over time was not an issue.

Session Generalizability

A second G study with the basic design might be called *session generalizability*. It would use as measurement occasions two subdivisions of some behavioral sequence (i.e., first and second halves or odd and even minutes) and would be an extension of the traditional split-half reliability study. In a split-half reliability study, recall that errors of measurement are confounded with differences between the two halves of the test or observation. In a session G study, differences between subdivisions of the behavioral sequence are estimated by the variance component for occasions. A session G study would be used to estimate the dependability of scores reflecting traits and behaviors expected to be stable during the course of the behavioral sequence being observed, although perhaps no longer than that.

Developmental Generalizability

A third G study with the same basic design might be called *developmental generalizability*. It would use as measurement occasions two or more administrations of the same instrument, perhaps at different ages or developmental stages. It is, then, an extension of the

traditional test–retest reliability study, which confounds measurement error with true changes in behavior that have occurred between the two administrations of a test. In this developmental G study, these changes in behavior over time would be estimated by the occasions facet of the design. The developmental G study is best suited to measure of traits or characteristics believed to be relatively enduring.

Use of Generalizability Coefficients

The comments made about the reliability studies discussed earlier can be repeated for these G studies. First, observational studies very rarely report data in G-study terms. The method does appear occasionally in dissertations (see, e.g., Leler, 1971; Mitchell, 1977), and it surfaces now and then in educational psychology research (Medley & Mitzel, 1963; McGaw, Wardrop, & Bunda, 1972). But to return again to developmental psychology as an example, there were no studies published in 1976 in either *Child Development* or *Developmental Psychology* that reported generalizability coefficients. Second, regardless of the sizes of the variance components for the facets, it is necessary to have a relatively large variance component for subjects to obtain a large generalizability coefficient. All other things being equal, a sample of subjects with greater variability on the trait being measured will yield a higher generalizability coefficient than will a sample of subjects with lesser variability on the trait.

The three G-study designs outlined here (duplicate, session, and developmental) all sample three important facets that may influence scores in observational studies: observers, observational methods, and occasions of observation. They differ in the nature of the occasions that are sampled, and these occasions tell us something about the nature of the universe to which scores can be generalized.

One way to contrast these universes is to imagine that the three types of studies were conducted so that exactly the same subjects, observers, and observational methods were used for all three. When only the nature of the occasions facet is different, one can hypothesize certain relationships among the sizes of the coefficients derived from the three studies. When duplicate G studies are conducted, it is expected that variance due to occasions will be the smallest and hence that the generalizability coefficient will be the largest. Further, when developmental G studies are conducted, it is expected that variance due to occasions will be the greatest and that the generalizability coefficients will be the smallest. Finally, when session G studies are conducted it is expected that the variance due to occasions and the resulting generalizability coefficients will be intermediate.

Other Uses for Generalizability Theory

Although measures of interobserver agreement and reliability have important uses in observational research, it should be clear from the earlier discussion that it is the generalizability coefficient that is potentially the most useful source of information about the quality of such data. Generalizability theory, however, has many applications of interest for the developmental psychologist other than the computation of a coefficient. Some of these applications are discussed below.

Multitrait–Multimethod Matrix

D. T. Campbell and Fiske (1959) introduced the notion of determining the validity of psychological measurement instruments by using a *multitrait–multimethod matrix.* As the name suggests, this matrix consists of scores for an individual on several traits, each trait assessed by two or more different methods. Such a design is clearly an instance of a G study in which traits and methods are the two facets. The data analysis proposed by Campbell and Fiske uses a matrix of correlations, but other authors (i.e., Kavanagh, MacKinney, & Wolins, 1971) have used analyses of variance with the multitrait–multimethod design. In this form, such a matrix closely resembles a G study.

The multitrait–multimethod matrix was used by Wicker (1975) to examine the reliability of observational records generated

from transcriptions of conversations. In this study observers were treated as "methods," and behavior samples were treated as "traits." By applying Campbell and Fiske's criteria to the correlational matrix, Wicker concluded that his data showed both convergent and discriminant validity.

Attribution of Variance

Traditionally, psychological studies have sought either to demonstrate mean differences between groups of subjects or to show consistent individual differences among subjects. Another kind of study, far less common, tries to systematically apportion the variance in a set of research data among several independent variables. This approach has been popular in efforts to resolve the issue of whether individual differences (personality) or situational differences (environment) are the most important determinants of human behavior. In such studies, data are gathered on a group of individuals in several situations. The relative importance of individual differences and of situational differences is estimated by the use of the statistic known as omega-square. As Golding (1975) has ably demonstrated, this experimental design is more profitably viewed as a G study; generalizability coefficients answer questions about the relative importance of different facets (here, individuals and situations) more suitably than does omega-square.

The logic involved in this kind of study is not limited to the person–situation controversy, of course. A similar question might be asked about a study in which several raters rate the behavior of a number of subjects. As Norman and Goldberg (1966) pointed out, these data can be interpreted as reflecting the behavior of the ratees (subjects) or the behavior of the raters. Once again, this study appears to be a straightforward, one-facet generalizability study in which raters is the facet. Although Norman and Goldberg did not use analysis of variance to analyze their data either, it is clear that the conceptualization is similar to that presented earlier: There are several sources of meaningful variation in a set of data, and only a multifacet study can illuminate the relative contributions of different facets.

Observer Generalizability

The use of generalizability coefficients to estimate the contributions of facets other than individual differences to a set of test scores has a particular application to observational studies. Specifically, it allows a researcher to look at the proportion of variance in scores that is attributable to the consistent behavior of the observers.

On the surface, the function of the generalizability coefficient sounds much like the function of the interobserver agreement percentage, but in fact it is not. Recall that the agreement percentage did not take into account the extent of overall variability in a set of data, whereas a generalizability coefficient does. It should be noted that the G study necessary to compute this coefficient is exactly the same study as that used to compute the more conventional coefficient based on the behavior of the subjects. Nothing has changed except one's point of reference.

Mitchell (1977) computed both subject and observer generalizability coefficients in a study in which 67 observers made repeated observations of 10 mother–infant pairs during the first year of life. She found that the coefficients reflecting the variability accounted for by observers were, in this study at least, greater than the coefficients reflecting subject differences. Although this result is specific to this particular set of data, the study is an example of the usefulness of observer generalizability coefficients.

Single-Subject Studies

Studies of individual subjects have had few ways of reporting reliability in the traditional sense. However, it is possible to conduct G studies using only a single subject. For example, several observers, several occasions, or several methods of observation might be used with a single subject. In this case, the generalizability coefficient would reflect the generalizability of a score recorded by a single observer under the circumstances sampled in the

study; that is, it would be an observer generalizability coefficient.

Such single-subject studies may be appropriate even when many subjects are part of a research project. It is commonly assumed that the behavior of all subjects is recorded with equal accuracy, that is, measurement errors are approximately equal for all subjects. If this assumption is true, then the data for all subjects are presumably equally "good." On the other hand, if this assumption is incorrect, so that subject behavior is recorded with variable accuracy, then data for different subjects may have different meanings.

The possibility of systematic differences in measurement error among subjects has been explored for traditional psychological tests (Ghiselli, 1963). Berdie (1969), for example, found that intraindividual variability (i.e., measurement error) was a stable trait for some pencil-and-paper performance tests. Ghiselli (1960) examined the prediction of "predictability." He was able to predict the errors of measurement for two groups of subjects on a reaction time test. Reliability for the high group was .97, compared with .82 for the low group.

A similar result was found in a quite different study by Gorsuch, Henighan, and Barnard (1972). Their interest was the internal consistency of a children's pencil-and-paper test of locus of control. They found that the reliability of the scale differed significantly according to the reading ability of the children. The errors of measurement were quite small for the good readers, but were large for the poor ones.

Observational studies, however, rarely have enough subjects to permit analysis of this kind. An alternative is to make use of observer generalizability coefficients. Suppose that the data collected for each subject were considered to be a mini-G-study. If the basic G-study design outlined earlier were used, each mini-G-study would have two facets (methods and occasions) that would be sampled for each observer. From each of these mini-studies it would be possible to compute an observer generalizability coefficient. Using this design, Mitchell (1977) found that although there were differences in observer agreement for different subjects, subjects did not differ in their observer generalizability coefficients.

Summary

Three different coefficients that purport to reflect the quality of data gathered in observational studies have been discussed. The first and most commonly used of these was observer agreement. Coefficients of observer agreement are a source of important information about the quality of observational data: the objectivity of different observers using the same method to record the same behavior. Determination of interobserver agreement is a necessary part of the development and use of observational measures. Interobserver agreement is not, however, sufficient by itself.

The second coefficient discussed was the reliability coefficient, obtained by fitting observational data into the pattern used by developers of standardized psychological tests. There are really many different reliability coefficients, each defined by the way the scores are obtained for its computation. Reliability coefficients provide useful information about the stability and consistency of individual differences among subjects, but confound measurement error with other sources of variability.

The third coefficient was the generalizability coefficient, as defined by Cronbach et al.'s (1972) multivariate theory. In one sense, a generalizability coefficient supersedes a reliability coefficient, because it too provides information about the stability and consistency of individual differences among subjects. Its superiority to the reliability coefficient lies in its ability to account for variance from sources other than individual differences and measurement error. Besides giving information that can be reported as the generalizability coefficient, a G study also permits innovative ways of looking at results from observational studies. These ways include variations on the multitrait–multimethod matrix, the attribution of variance to independent variables, observer generalizability, and studies of single subjects. It is therefore especially unfortunate that G-study designs are not used more frequently in observational research.

Recommendations

Researchers doing observational studies are obliged to show that their measuring instruments are reliable—that they have small errors of measurement and that the scores of individuals show stability, consistency, and dependability for the trait, characteristic, or behavior being studied. The reason for this obligation is practical: If the measure is not reliable, it cannot be expected to show lawful relationships with other variables being studied. It is well-known that the reliability of a standardized test sets the limits of its validity (Nunnally, 1967). Similarly, the predictive usefulness of observational measures is limited by the stability and consistency of the scores obtained from the observational instruments.

Observer agreement coefficients alone, regardless of their mathematical sophistication, are inadequate to demonstrate this stability and consistency. What alternative or additional information ought to be reported in observational studies, and how should it be collected?

First, and most basically, the coefficients computed should be based on the same scores that are used in the substantive analysis of the study. If a composite score (such as a total of several categories or time units) is to be used for analysis, it is this composite—and not its component individual categories or time units—that should be examined for agreement, reliability, or generalizability. Of course, during the training of observers it is extremely helpful to compare the records of different observers on a trial-by-trial (or time unit by time unit) basis, but such a comparison does not suffice for reporting in a published research article. It is possible, albeit rare, to have acceptable agreement on a time unit basis and yet unacceptable levels of agreement on a total score. It is also possible, and much more common, for observers to be in only moderate agreement for small time units, but to show good agreement for a total score. In this case, an analysis of the trial-by-trial agreement would underestimate the agreement for the measures actually employed in the study.

Similarly, if several different scores are to be analyzed, coefficients should be computed for each of them. Good agreement or reliability on the frequency of particular behaviors, for example, does not insure good agreement or reliability on their duration. The data that are to be analyzed are the data that should be scrutinized for their stability and consistency.

Second, the coefficients should be computed from data that are part of the actual study being reported. The studies of observer agreement cited earlier (i.e., Reid, 1970; Romanczyk et al., 1973; Taplin & Reid, 1973) show clearly that the quality of data collected during a study may not be the same as the quality collected during reliability assessment or training. This difference can also be expected for data collected during a pilot study or during a previous study that used the same instrument.

This means that the researcher must plan to collect data that can be used to compute coefficients of agreement, reliability, or generalizability at the same time the rest of the data are gathered. Although this does entail some additional data collection, the addition need not generally be enormous (see, e.g., Rowley, 1976).

Third, interobserver agreement should always be obtained and reported. In most observational studies, observer disagreement is an important source of error, and it should be carefully and systematically monitored. This monitoring needs to be regular and unobtrusive for the most accurate results. Researchers also need to be alert to the possibility that interobserver agreement may differ for different subjects, therefore observations from many—preferably all—subjects should be used when determining the level of agreement.

Although the observer agreement percentage is the most widely used and most easily computed index of agreement, it may be desirable in some cases to substitute other indices, such as that suggested by Lawlis and Lu (1972). Whatever the exact form of the coefficient, however, both the researcher and the reader should remember that it reflects only one source of error and that it reports this error in absolute rather than in relative terms.

Fourth, a reliability or generalizability

coefficient that uses two or more measurement occasions should be presented for any score that is used to predict other behavior. The researcher is obliged to demonstrate that the individual differences among subjects are stable over different occasions as well as over different observers. This stability can be reported as a split-half, alternate-forms, or test–retest reliability coefficient, or as a session or developmental generalizability coefficient. The single exception to this rule is a study that focuses on some behavior not expected to show stability over time (e.g., first response to a new stimulus). In this case only, an interscorer reliability coefficient or a duplicate generalizability coefficient is appropriate.

It is impossible to overemphasize the importance of using two or more measurement occasions to compute coefficients of reliability or generalizability. The purpose of reporting such a coefficient is to demonstrate that the data being analyzed reflect stable, consistent, and dependable individual differences among subjects. If, however, a single measurement occasion has been used, then the coefficient can demonstrate only the competence and consistency of the observers. Since many, if not most, observational studies obtain repeated measures as part of the experimental design, it is seldom necessary to collect additional data. What is necessary is to analyze and report these observational measures in terms of their stability over time.

Fifth, a generalizability study is usually preferable to the computation of a reliability coefficient. First, a G study provides more useful information about sources of variability in a set of data than does a reliability coefficient. Leler (1971), for instance, used the variance components from a G-study analysis midway through her research to help refine the observation instrument and to retrain observers on some items. Second, the G-study design makes other kinds of analysis possible for most observational studies. These include, particularly, observer generalizability coefficients and coefficients for individual subjects.

Finally, the design of the generalizability study should correspond to the overall design of the research. The G study for most applications does not need to be complex. Two facets—observers and occasions—are usually sufficient. There are some studies, however, that require three-facet designs.

Studies that measure behavior before and after some intervention (experimental treatment) should include a third facet in the G study—before versus after the intervention. This is especially important if the intervention is likely to reduce the variability of the observed behavior. For example, suppose a study were undertaken to reduce the amount of aggressive behavior exhibited by school children on the playground. At the start of the study, the children would be quite variable in their playground aggression. If the intervention were successful, however, the variability after intervention would be quite low (all kids showing low aggression). A measure that would be quite reliable (in the classical sense) in differentiating among the children before the intervention might be inadequate afterwards. The G-study design allows the researcher to evaluate this possibility.

In the same way, studies that compare two groups of subjects should include group membership as a third facet in their G study; that is, it is necessary to demonstrate that the scores for both groups show approximately equal stability and consistency over different occasions and different observers.

Conclusions

These recommendations have an important empirical implication: Studies that follow them will report coefficients that are lower, perhaps substantially lower, than the coefficients reported by studies that do not follow them. The procedures suggested here are stringently conservative, and the coefficients that they yield should be considered lower limits of the true dependability of the observational data that are collected. Reviewers and readers, who are used to seeing reports of observer agreement in the .80s and .90s, will have to change their expectations for reliability and generalizability coefficients, which will often be in the .50s and .60s. In fact, these new coefficients are not low; rather the old ones were inappropriately high. Observer agreement percentages, interobserver reliabil-

ity, and reliability or agreement determined during pretests or previous studies are all spuriously high estimates of the quality of the data that are collected. Although we may have to revise our standards downward concerning the size of reported coefficients, we will be revising our standards upward concerning the ways in which the data for the coefficients are gathered and analyzed.

There is a methodological implication of these recommendations as well. Most observational studies currently being published are pretty straightforward in experimental design. Their sophistication is usually based on the nature of the observations themselves: the complexity of the behavioral record, the length of time included in the record, or the specific nature of the situation or setting in which the data are gathered. Future studies that follow the recommendations given here will be far more complex in design than is now typically the case.

One final question concerns whether it is really worth the additional time and money necessary to determine and report on the quality of the data in the ways suggested here. If including a G-study design in an observational study has no benefits except the computation of a generalizability coefficient, the answer is probably no. In fact, though, including a G study usually provides a great deal of substantive information to the researcher. Are there differences in the behavior reported by different observers? Do subjects act differently on different occasions? Is the variance of the data different before and after an experimental treatment? Are all groups in this study represented by data of equal quality? All these important questions can be addressed by including a G study in the overall research plan.

Even more importantly, though, the use of generalizability designs focuses the attention of the researcher (and the reader) on both the individual differences among subjects and on the influence of other (usually environmental) factors on behavior. As Cronbach (1957) eloquently pointed out, psychologists have historically tended to focus on one or the other of these two aspects: individual differences (using correlational methods) or group differences (using experimental methods). Fittingly, it is now Cronbach's theory of generalizability that makes it possible to combine these two viewpoints. And observational research is particularly well suited to the task of looking at individual differences in behavior in the context of systematic environment variation.

The Dichoptic Viewing Paradigm: Do the Eyes Have It?

Gerald M. Long
Stanford University

The two-part logic underlying the use of the dichoptic viewing procedure as a "psychoanatomical" tool by which to infer the retinal or cortical locus of critical processes for the perception of some visual phenomenon is reviewed and analyzed. Serious logical weaknesses are identified in both sides of the dichoptic argument: the inference of dominant retinal processes from unsuccessful dichoptic viewing or dominant cortical processes from successful dichoptic viewing. Specific examples from the visual literature are used to demonstrate the potential confounding of each of the variables suggested in this critique. The dichoptic viewing procedure tends to be employed in too uncritical a manner, and the usual interpretations of studies that have used this procedure as the sole technique by which to infer the general locus of a given visual phenomenon may be seriously in error.

Interest in localizing the physiological structures or levels within the visual system that are most directly involved in various perceptual phenomena has been directing research and theory since some of the earliest experimental work in vision (cf. Helmholtz, 1909/1962). However, this interest has taken on a renewed vitality in recent years with regard to the currently dominant information-processing conceptualization of perceptual functioning (e.g., Haber, 1969, 1974; Lindsay & Norman, 1972). In this now prevalent view, various stages and processes, usually in some form of hierarchical arrangement, by which stimulus information is transformed and transmitted in the visual system are hypothesized. Whether such stages purely represent intervening variables and thereby serve simply heuristic and shorthand functions for conceptualizing a cluster of logical processes or whether they actually refer to potential structures or groups of structures in the physiological system is frequently unspecified. Hence, the ultimate utility of these hypothetical processing stages in terms of a realistic conception of the physical system modeled is unclear. Julesz (1971) has recently provided an extremely lucid and detailed exposition of the value of a program of research aimed specifically at localizing within the visual system the physiological level(s) of processing involved in the perception of all manner of phenomena—from vernier acuity to eidetic memory to visual illusions. Julesz was particularly concerned with the potential roles random-dot stereograms and related techniques can play as psychoanatomical procedures by which the retinal or cortical locus of various visual percepts can be inferred from nonphysiological manipulations. However, a much older and in some sense related technique that is still very popular among researchers for ostensibly assessing the peripheral versus central locus of a visual percept is that of dichoptic viewing.

The author wishes to express his appreciation to B. Farrand, C. Krumhansl, N. Hersh, R. Schumer, and two anonymous reviewers for their helpful comments on earlier drafts of this article.

Requests for reprints should be sent to Gerald M. Long, who is now at the Department of Psychology, Villanova University, Villanova, Pennsylvania 19085.

Dichoptic Viewing Paradigm

Since at least the time of Helmholtz (1909/1962) it has generally been believed that the ability or inability of the visual system to combine information presented separately to

the two eyes can reflect directly the locus in the visual system of the processes involved. This dichoptic viewing procedure, which is sometimes also referred to as binocular or stereoscopic viewing, typically consists of the independent stimulation of the two eyes, either simultaneously or successively, by two aspects of the stimulus array that define some perceptual phenomenon.[1] Two rather well-known examples should clarify the procedures involved as well as the usual conclusions reached from this experimental manipulation. For a case of simultaneous dichoptic viewing, consider the interesting and sometimes controversial phenomenon known as *binocular yellow*. Under appropriate conditions, if a green stimulus is presented to one eye and an identical red stimulus is presented to the other eyes, the observer will frequently report a sensation of yellow. This is basically the same subjective sensation that occurs when both colored stimuli are presented to the same eye. The implications of this demonstration were clearly appreciated by early theorists in color vision. For Hecht (1928), this simple result exposed a critical weakness of the Hering (1964) and Ladd-Franklin (cited in Boring, 1942) theories, both of which required special retinal receptors for yellow light. On the other hand, the Young-Helmholtz three-receptor theory (cf. Boring, 1942) was sufficient to account for the phenomenon with the simple assumption that under the experimental conditions, "the red sensitive fibers and the green sensitive fibers are both active and the brain synthesizes yellow" (Hecht, 1928, p. 238). The seriousness of this attack for the other color theories was readily apparent to their proponents, and heated rebuttals to the dichoptic demonstration, stressing alleged procedural and stimulus weaknesses, were raised (Murray, 1930, 1939). Based on subsequent, more controlled experiments (e.g., F. H. Thomas, Dimmick, & Luria, 1961) and, of course, with the wisdom of hindsight bolstered by 40 intervening years of research, (e.g., P. K. Brown & Wald, 1964), it is not difficult to side now both with Hecht's argument for the authenticity of binocular yellow and the underlying three-pigment basis to normal color vision.

For an example of successive dichoptic viewing, there is the extensive literature on dichoptic visual masking (e.g., Turvey, 1973). In the usual dichoptic masking experiment, the target or test flash is presented to one eye, and the mask is presented, following a variable interstimulus interval, to the other eye. Perceptual performance (e.g., probability of detection or percentage of letters correctly reported) is then compared under the same temporal conditions with that obtained when both parts of the stimulus array, target and mask, are presented to the same eye (monocular viewing) or to both eyes (binocular viewing).[2] If there is very little difference between the dichoptic and monocular (or binocular) masking conditions, *postretinal* processes are usually inferred to underlie the masking effect. Hence, the masking of letters with complex patterns has been hypothesized to involve cortical processes, because of the general comparability of monocular and dichoptic demonstrations (cf. Breitmeyer & Ganz, 1976). On the other hand, if it is not possible to mask a target presented to one eye with a mask presented to the contralateral eye, *retinal* processes are inferred to dominate in any masking effects with the same stimuli obtainable under normal viewing conditions.

---

[1] A slight variation on this usual dichoptic approach, which is discussed at a later point in the article, should perhaps be mentioned here. Basically, it involves the presentation of the complete visual phenomenon to one eye (e.g., flickering light for critical flicker frequency determination) while some other stimulus is presented to the other eye (e.g., variable luminance background). If perceptual performance with the phenomenon is affected by the latter stimulus to the contralateral eye, central or cortical interactions are assumed to be involved (cf. J. L. Brown, 1966b).

[2] In some of the older literature, the term *binocular* was used in the same sense that *dichoptic* is used in the present context (e.g., Ammons & Weitz, 1951; Kahneman, Norman, & Kubovy, 1967). Correspondingly, phrases like *binocular interaction* or *binocular fusion* frequently referred to the visual system's processing of separate (i.e., dichoptic) stimuli presented to the two retinas. This usage of the word *binocular* appears subject to unnecessary confusion. Therefore, in the present article, *binocular* viewing is reserved for those conditions in which a single optic array is presented simultaneously to the two eyes, that is, normal viewing conditions.

Thus, homogeneous field masking (by a bright, blank field) has been relegated to intraretinal factors (cf. Breitmeyer & Ganz, 1976).

From these two examples, the reasons for the popularity of the dichoptic viewing paradigm are probably apparent. Theoretically, the two possible outcomes of such a procedure permit distinct conclusions: (a) If the visual phenomenon in question has remained essentially unchanged (although perhaps somewhat weakened in the dichoptic viewing condition), it is assumed that central (i.e., cortical) processes largely underlie the phenomenon, since only in postretinal centers is the separate input from the two eyes known to be combined; (b) on the other hand, if dichoptic presentation of a phenomenon destroys the usual percept, it is generally argued that the critical processes that determine the usual visual effect must be retinal or at least precortical. Peripheral processes are inferred, because the combination of the two half stimuli must apparently occur prior to the level of binocular innervation for adequate perception of the phenomenon in question. Needless to say, the latter conclusion that a given visual phenomenon is retinal does not mean that central stages are unnecessary; the perception of any event requires central structures. (In the extreme case, regardless of how perfect the functioning of the two eyes, if the cortical and subcortical structures are inoperative, one is blind to all visual phenomena.) Rather, the dichoptic viewing procedure has been employed to determine whether the central processing of the separate retinal signals from the half stimuli presented to different eyes is sufficient or whether peripheral structures must process certain aspects of the stimulus event in combination prior to the involvement of the higher centers. In other words, if a given visual event is not able to be perceived dichoptically, a nonlinear system has been inferred in which the result of the processing of A (input to left eye) + B (input to right eye) is not equivalent to the processing of A + B, the combined input to either eye alone.

Although the dichoptic viewing paradigm has had a considerable history, it was employed extensively by the Gestalt psychologists as the basis for an interocular criterion (Pastore, 1971) with which to demonstrate that more was involved in the perception of many phenomena than met the eye. Wertheimer (1912), for example, demonstrated that apparent motion was easily obtained even if the sequential stimuli were presented to separate eyes, thereby excluding interactions between adjacent retinal regions as a necessary basis for the phenomenon. Similarly, Köhler (1940; Köhler & Wallach, 1944) used the dichoptic paradigm in his work with figural aftereffects to argue that "the effect is located in the brain, where processes which are due to stimulation of corresponding parts of the two retinae occur in a common area" (1940, p. 86). However, these early references should not give the impression that the dichoptic procedure is in any way a paradigm of the past or that it is restricted to a very limited category of visual phenomena. The popularity of this psychoanatomical procedure by which one is theoretically able to infer the locus of critical processes for a large number of visual effects has remained quite strong up to the present day. Employing the two-part logic outlined in the previous paragraph, other researchers have used the dichoptic viewing paradigm to investigate the locus and nature of afterimages (e.g., Hansen, 1954), flicker discrimination (e.g., G. J. Thomas, 1955), apparent motion (e.g., Shipley, Kenney, & King, 1945), temporal summation (e.g., Kahneman, Norman, & Kubovy, 1967), Ganzfeld effects (e.g., Hochberg, Triebel, & Seaman, 1951), masking and metacontrast (e.g., Alpern, 1953; Turvey, 1973), geometric illusions (e.g., Papert, 1961; Schiller & Wiener, 1962), McCollough and related contingent aftereffects (e.g., Skowbo, Timney, Gentry, & Morant, 1975), short-term visual storage (e.g., Meyer, Lawson, & Cohen, 1975), frequency- or size-specific visual channels (e.g., Harter, Towle, & Musso, 1976), and many other visual phenomena. However, it should be noted that this technique's popularity has continued in spite of specific criticisms that have been raised against various aspects of the argument on which the dichoptic procedure is based. The present article attempts to outline these generally over-

looked weaknesses in the dichoptic procedure that serve to question subsequent conclusions concerning the locus of the critical processes underlying certain phenomena.

As a final comment before presenting these proposed weaknesses in the experimental procedure, it is of interest to note that previous critics of the dichoptic viewing paradigm appear to have focused on difficulties with one or the other of the two conclusions described above, while allowing the other to remain. For example, as is treated in more detail below, Julesz (1971, p. 6) tended to accept as probably "well-founded" the inference of critical cortical processes if the dichoptic viewing of some phenomenon is unimpaired, while rejecting the inference of dominant retinal processes if dichoptic viewing fails. Kolers (1972), on the contrary, argued that the dichoptic procedure only permits one to make the negative case:

> Failure to obtain a percept dichoptically proves only that most of the processing occurs early in the visual channel; but the occurrence of a percept dichoptically never proves the reverse, that all of its processing is normally cortical. (p. 182)

In other words, these two researchers will only accept the opposite conclusions from a dichoptic viewing experiment. In light of these differences of opinion concerning the legitimacy of either side of the dichoptic argument, it is the purpose of the present article to outline the rather strong case that can be made against drawing either of the usual conclusions from the dichoptic viewing experiment. Furthermore, to illustrate the points raised in this article, research examples from the current vision literature that appear potentially subject to some of the logical flaws to be described are employed.

The Negative Result: Does the Inability to Obtain a Percept Dichoptically Indicate Critical Retinal Processes?

Binocular (Retinal) Rivalry

As mentioned above, Julesz (1971) criticized the logic of inferring exclusive retinal processes as the basis of a given visual phenomenon if dichoptic viewing fails (i.e., if the normal percept cannot be obtained dichoptically). The reason for this involves the unknown role of binocular rivalry under dichoptic viewing conditions. It is well-known that if quite different information is presented to the two eyes, rather than simple fusion of the dichoptic images, the input from one eye may be partially or entirely suppressed while that of the other eye dominates (cf., Hochberg, 1972). Since it is very difficult to predict under which conditions fusion as opposed to suppression of separate retinal inputs will occur, binocular rivalry remains a serious confounding variable in the dichoptic viewing paradigm. Any change observed under dichoptic conditions may result from *interocular* suppression rather than from an assumed absence of critical *intraocular* processing presumably necessary for the usual percept.

Several indications of the potential involvement of binocular rivalry under conditions of dichoptic viewing can be found in the extensive masking literature. For example, Schiller and Smith (1968) reported greater masking effects in a metacontrast paradigm with dichoptic viewing than with monocular viewing. They interpreted this rather unexpected result in terms of binocular rivalry effects between the "test" eye and "mask" eye in addition to classic metacontrast suppression effects. Typically, influences from interocular rivalry are not considered in such work, but in this particular case, the additional hypothetical component of binocular rivalry was deemed necessary because the dichoptic suppression effect was larger than that of monocular suppression. Nevertheless, this does serve to emphasize the unknown contribution of binocular rivalry in those studies that report any effect of dichoptic viewing. Moreover, further evidence for ocular suppression during dichoptic viewing has been demonstrated convincingly in a recent study of masking effects by Monohan and Steronko (1977). In an attempt to control for binocular rivalry effects resulting from chronic ocular dominance of one eye over the other within subjects, these investigators preselected subjects on the criterion of equal masking effects across the two eyes before de-

termining luminance effects in a dichoptic pattern-masking experiment. Only 9 of 24 subjects tested met this criterion, but with these subjects results were obtained that were at odds with those previously reported in the masking literature. On the basis of these results, Monohan and Steronko argued for the reinvestigation of all reported dichoptic masking effects in which binocular rivalry, especially as reflected in ocular dominance, has not been controlled. It is proposed that this same argument should be given serious consideration with regard to other visual phenomena for which dichoptic viewing in any way alters performance.

In the context of the binocular rivalry argument, Julesz (1971) described the value of the random-dot stereograms that contain little monocular form information and thereby appear to eliminate or at least reduce binocular rivalry effects. To emphasize this point, Julesz criticized those studies investigating geometric illusions that inferred the dominance of retinal processes in these illusions because of the reduced illusory effect under dichoptic viewing conditions (e.g., Springbett, 1961). Following Day's (1961) argument that such findings may have resulted from binocular rivalry effects, Schiller and Wiener (1962) found that when brief tachistoscopic flashes of the geometric illusions were employed to reduce rivalry effects in the dichoptic situation, the magnitude of the illusory effects approached that obtained under binocular presentation. Using random-dot stereograms, Papert (1961) and Hochberg (cited in Julesz, 1971) reported these same illusions to be basically identical under classical (i.e., binocular) and cyclopean (i.e., stereogram) stimulation. Such results serve to confirm Julesz's argument that the earlier investigations were confounded by unknown effects of binocular rivalry under the dichoptic viewing conditions. However, it should be mentioned that even with the random-dot stereograms, the absence of successful stereoscopic viewing of some phenomenon only allows one "to conjecture its peripheral origin until it is proven to be central" (Julesz, 1971, p. 4). This caution is necessary because, although unimpaired dichoptic viewing may indeed reflect basic superposition of the retinal signals at central levels, the possibility of even partial binocular rivalry cannot be completely eliminated. The need for this caution is further supported by a recent study by Blake (1977) that demonstrated temporary suppression of an above-threshold target presented to one eye by a target at its own threshold contrast in the other eye. Hence, the extreme sensitivity of the mechanism that underlies ocular suppression appears to strengthen the argument against assuming an absence of binocular rivalry under any dichoptic viewing conditions.

Monocularly Innervated Cortical Effects

A second possible criticism of inferring retinal processes from a failure of dichoptic viewing is of a somewhat more hypothetical nature, but is nevertheless consistent with current physiological evidence. Hubel and Wiesel (1962, 1968) reported that the majority of cortical cells from which they recorded with microelectrodes were binocularly driven cells. However, a good proportion of their sample (up to 30%) appeared to be innervated only by one or the other eye. This, in turn, raises the possibility of some visual effects that may involve these monocularly driven cortical cells alone. Such visual effects would not be observable under conditions of dichoptic viewing, but would nevertheless be critically dependent upon postretinal processes. In support of this contention, it has recently been argued that color-contingent motion or orientation aftereffects may well fall into this category (Favreau & Corballis, 1976; Skowbo et al., 1975). In a typical demonstration of the color-contingent motion aftereffect (e.g., Mayhew & Anstis, 1972), a red clockwise-rotating spiral is alternated with a green counterclockwise-rotating spiral during the adaptation phase. In the subsequent test phase, if a stationary red spiral is viewed, it will appear to rotate counterclockwise; a stationary green spiral will appear to rotate clockwise. However, if during the adaptation phase the color is presented to the left eye and the rotating spiral to the right eye, no aftereffect is observed when the spiral

is subsequently viewed by the right eye (Murch, 1972). Hence, even though there is considerable evidence that these aftereffects are nonretinal (cf. Skowbo et al., 1975), it does not appear possible to innervate the appropriate cortical centers with the dichoptic presentation of the stimulus components during the adaptation phase. Whether future research will support these results with the dichoptic viewing of certain color-related aftereffects is not critical to the argument proposed here. The possibility of visual effects dependent even only in part on monocularly innervated cortical cells serves to weaken inferences of critical retinal processes that are based purely on the failure of dichoptic viewing.

The Positive Result: Does the Finding of No Difference Between Normal and Dichoptic Viewing Indicate the Relative Dominance of Central Processes?

Just as the previous two arguments have been raised against inferring dominant retinal processes from a failure of dichoptic viewing, it is also possible to find fault with the other side of the dichoptic paradigm by which cortical processes are inferred to play the critical role in the perception of some phenomenon if dichoptic viewing leaves a percept relatively unaffected. In this section various arguments, with examples from empirical work, are developed that seriously question this other half of the dichoptic paradigm.

Phenomenal Overlap of the Monocular Visual Fields

This first criticism can perhaps best be explained by reference to the controversy that existed for several years concerning the central versus peripheral locus of simple afterimages. As early as Newton, it was known that if an intense light source is viewed for a few seconds with one eye that is then closed and the nonstimulated eye is used for viewing, a negative afterimage of the source can sometimes be seen (e.g., Day, 1958; Terwilliger, 1963; Walls, 1953). This apparent *interocular transfer* of the afterimage was cited by some as evidence for central involvement in such afterimages (cf. Day, 1958). However, the bulk of both empirical and theoretical work favors the notion that the retina is the locus of classic afterimages (J. L. Brown, 1966a; Craik, 1940). If it is assumed that afterimages are due entirely to retinal fatigue, the problem arises as to the basis of the *phenomenal* transfer of such retinally based effects. In a footnote to his well-known study that investigated adaptation or aftereffects to curved lines, Gibson (1933) suggested the potential involvement of binocular rivalry in the apparent transfer of classic afterimages such that the stimulated but closed eye may dominate the open eye under some conditions. Sumner and Watts (1936) developed the argument more explicitly and found empirical support for this proposal by investigating differences in the apparent transfer of afterimages under various stimulus and background conditions. Day (1958) extended the argument even further and generalized its significance to all dichoptic viewing situations that involve aftereffects by stressing the possible confounding effect of the phenomenal overlap of the visual fields from the two eyes. In other words, Day argued that it is questionable to infer central processes from "successful" dichoptic viewing because it is not generally possible for the observer to separate truly centrally transferred effects from continued input from the closed but still signaling eye because of the overlap of the visual fields from the two eyes. This overlap of the two monocular fields has been proposed as the basis of the apparent transfer of negative afterimages, since the retinal pattern outlasts the physical stimulus whether the stimulated eye is open or closed following termination of the stimulus. Delabarre (1888) expressed strongly this same weakness of the dichoptic procedure 12 years before the turn of the century:

> A serious difficulty in settling the question [of the locus of afterimages] lies in the well-known impossibility of separating the visual fields of the two eyes. Whether one eye or both are open, whether they are focused on the same point or are held parallel, or squinted, or even jammed into all sorts of relative positions by fingers inserted into their sockets, the field of each will appear to coincide with the field of the corresponding portion of the retina of the other. (p. 326)

Much later, Terwilliger (1963) stressed the implications of these findings with afterimages for the study of other visual phenomena for which dichoptic viewing has proved successful. He argued that if a phenomenon with such a clearly retinal basis as afterimages exhibits introcular transfer, it does not appear theoretically sound to exclude categorically the involvement of retinal factors in any visual effects simply on the basis of successful dichoptic viewing. Terwilliger was specifically concerned with the possibility of an important retinal contribution to figural aftereffects, a notion rejected previously by Köhler and Wallach (1944) on the basis of their findings with dichoptic viewing described above. His methodological cautions, however, appear generally valid for all studies that employ the dichoptic procedure. Nonetheless, they are perhaps given further credibility by the subsequent emergence of alternate theories of figural aftereffects that stress the role of dominant retinal processes in such perceptual distortions (e.g., Deutsch, 1964; Ganz, 1966a, 1966b). Hence, as with afterimages, the use of the dichoptic viewing procedure may have retarded the development of an adequate theory of figural aftereffects by the uncritical inference of a retinally independent basis to the phenomenon solely on the basis of successful dichoptic viewing.

The potential confounding of the phenomenal overlap of the visual fields may seem rather obvious in retrospect, but it should be remembered that the question of the locus of afterimages was debated for years because of such apparent interocular transfer of the phenomenon. Furthermore, although it may appear implausible that this same problem could arise in current research, a much more subtle form of this criticism is less difficult to appreciate.

Hierarchical Cortical Processing of Retinal Signals

This less obvious—and therefore perhaps more dangerous—form of criticism against the inference of dominant cortical processes from successful dichoptic viewing was alluded to by Day (1958), but has been more recently and explicitly raised by Julesz (1971) and Sakitt (1976). It is a criticism based on the notion of successive stages within the visual system (i.e., levels of information processing) and rests on two logical premises. First, it must be remembered that one's ability to perceive a single unified (and three-dimensional) world from two separate retinas with overlapping visual fields results to a large degree from the eventual combinations of the two inputs at higher brain centers. This cyclopean conceptualization appears consistent both with current neurophysiological (e.g., Barlow, Blakemore, & Pettigrew, 1967; Pettigrew, 1972) and with psychophysical (e.g., Blake & Fox, 1973; Ono, Angus, & Gregor, 1977) evidence. Second, as mentioned earlier, it should be noted that one's awareness of some visual stimulus, no matter how completely dependent on retinal processes, results from the involvement of postretinal centers in the visual system. In the context of postulating the physiological basis for iconic memory, Sakitt (1976) made the distinction between the locus of the perception of some visual effect and the physical locus of the effect itself. Postretinal processes are necessarily involved in the former, yet a researcher frequently attempts to infer the latter from various experimental procedures such as the dichoptic viewing paradigm. To clarify further this distinction between the locus of a visual effect and the locus of the perception of that effect, consider the classic demonstration by Craik (1940) involving afterimages. He was able to show that although afterimages could be established without subjective awareness by temporarily pressure blinding the stimulated eye, higher centers were necessary for the awareness of the afterimage. Even retinal fatigue requires postretinal centers for subjective appreciation.

These two points simply reflect the basic fact that one's normal two-eyed perception of the world typically results from the eventual involvement of binocularly innervated cortical centers that in some way combine the inputs from the two retinas. Now, with regard to the dichoptic viewing paradigm, suppose a particular visual manipulation results in some change (unspecified) in the retinal signals in just one eye. These signals

will be transmitted to the higher centers in the visual system, where they may then interact with whatever signals are arriving from corresponding retinal regions of the other eye. Electrophysiological recording at the single-cell level in the striate cortex of the cat has demonstrated the existence of *binocular interaction fields* of excitatory and inhibitory regions that describe the activity of a simple cortical cell as a function of the relative stimulation of both eyes (Bishop, Henry, & Smith, 1971). The point is that dichoptic viewing of some visual phenomenon may appear to reflect critical central processes even though retinal factors may dominate and largely define the phenomenon. This results from the basic fact that one's awareness of the visual world necessarily involves postretinal structures, and in these successive postretinal stages of information processing, monocular inputs are eventually combined. Hence, an experimental procedure that can tap directly only postretinal processing (i.e., observers' verbal reports) may overestimate the cortical contributions to some visual phenomena because of the interaction between incoming retinal signals. This is a serious weakness of the dichoptic viewing procedure.

To illustrate the potential confounding of this relatively late combined processing of retinal inputs, it may be best to focus on those studies that have employed a slight variation of the usual dichoptic procedure (see Footnote 1). In these studies, some complete visual pattern is presented to one eye, and the effect of introducing some other stimulus to the other eye is determined. If this latter stimulus has some effect on the perception of the stimulus to the first eye, purely central processes are inferred to be involved. For example, Jacewitz and Lehmann (1972) presented a typical Sperling (1960) partial-report task to an observer's left eye while varying the input to the right eye from that of a blank field to a train of either blank or grid flashes. For the partial-report task, nine letters in a 3 × 3 array were presented for 50 msec, followed at some brief delay by a variable-pitch tone that directed the observer to report the top, middle, or bottom row of letters only. The average number of letters available to the observer (i.e., the percentage of the three letters correctly reported per trial times the total number [nine] presented per trial) was then estimated for each time delay condition and as a function of the three visual conditions for the contralateral eye. The decrease in recall performance with increasing complexity of the contraocular signals was interpreted in terms of reduced central processing capacity available; and, hence, the cortical locus of the iconic memory theoretically assessed by the partial-report procedure was concluded. Similar logic underlies the use of an analogous procedure in the study of critical flicker frequency (CFF). Variations in the values of CFF for a given intermittent stimulus presented to one eye when the input to the other eye is varied "are presumed to reflect central interaction processes" (J. L. Brown, 1966b, p. 259).

In some cases, the conclusion of dominant cortical processes from these studies may well be correct. However, the above brief quote by Brown reveals a potential flaw. What is central, the phenomenon itself, or just the interaction with the contraocular signals? Did Jacewitz and Lehmann in the study described previously demonstrate the cortical locus of the persistence required on the iconic memory task or the cortical locus of the interference from the other retinal signals? These uncertainties can be stated more formally within an information-processing framework (cf. Haber, 1974). Given a hierarchical arrangement of processing stages (both retinal and cortical) within the visual system, the dichoptic procedure cannot clearly distinguish between visual effects whose dominant processes are cortical and those whose processes are only partly cortical or even those for which retinal processes are most critical. Some examples from the current visual literature should help to clarify this interpretive difficulty.

Example 1: Spatial frequency channels in the visual system. Consider the recent study by Harter et al. (1976) in which different checkerboard patterns of various sizes were presented dichoptically to the two eyes. Visual evoked potentials and reaction times to a checkerboard pattern that was flashed to the left eye were determined as a function of the checkerboard size in that pattern and as

the size of a constant checkerboard pattern viewed by the right eye was varied. Both response measures indicated reduced sensitivity to a pattern presented to the left eye when that pattern was most similar to the pattern viewed by the right eye. The authors concluded that the results were consistent with the notion of binocularly innervated, size-specific cortical neurons, which were selectively adapted by the pattern presented to the right eye.

It is not the purpose of the present discussion to dispute the specific conclusions of the Harter et al. study. As they pointed out, there is considerable converging evidence from other studies for the same conclusion; so, in fact, there may be good reason to accept their proposal. Rather, the importance of the Harter et al. study in the present context is to demonstrate the plausibility of an alternate explanation of dichoptic results based upon the particular weakness of the dichoptic procedure that concerns the ultimate combination of retinal signals prior to an observer's response. In this regard, consider the predicted results if there were only retinal size-specific cells—perhaps the retinal ganglion cells with their concentric receptive fields of varying size. A fatiguing of one such set of cells in the right eye could result in increased noise or inhibitory signals being transmitted to the higher centers, thereby affecting the ultimately perceived input from the left eye. Hence, given the phenomenal overlap of the monocular visual fields and the eventual convergence of ocular signals at cortical levels prior to awareness, it would be possible to explain the same pattern of results in terms of size-specific retinal processes. Unique processing by cortical centers need not be inferred. Moreover, consider the likely pattern of results if the above study had employed simple homogeneous fields of varying luminance levels also presented dichoptically. Results similar to those of Harter et al. that reflected a depression in performance with increasing test (left eye) and background (right eye) similarity would most likely be expected, but it is highly doubtful that such results would be interpreted in terms of the existence of binocularly innervated, luminance-specific cortical neurons. Before proposing such a construct, a researcher would first wish to rule out in some way the known retinal effects of varying luminance.

Several other studies that probed the nature of the hypothesized spatial frequency (or size-specific) channels in the visual system also employed dichoptic techniques as experimental means by which to infer the locus of such effects. Blakemore and Campbell (1969) and Blakemore and Sutton (1969) demonstrated the interocular transfer of adaptation effects that were spatial frequency specific, theoretically reflecting the adaptation of a narrowly tuned, binocularly innervated cortical channel. More recently, Blake and Levinson (1977) demonstrated interocular facilitation of grating detection (i.e., lowered threshold contrast for a monocular, striped target by the presentation of a subthreshold grating to the other eye). This effect also was spatial frequency specific: Optimal facilitation was found when the gratings to the two eyes were most similar. Although these studies may indeed share some of the weaknesses of the dichoptic procedure detailed previously, there are other critical factors that render their dichoptic procedure considerably less suspect. On the other hand, as mentioned in the context of the Harter et al. (1976) study, there is significant converging evidence both from other psychophysical studies and from electrophysiological investigations that supports the cortical locus of neurons in the visual system that are selectively sensitive to the spatial frequency of a retinal stimulus (cf. Blake & Levinson, 1977). However, even more important is the fact that in the three studies just cited, an additional empirical result was also stressed that substantiates the postretinal interpretation of the locus of such effects. Specifically, the interocular effects described in these studies were also found to demonstrate *orientational selectivity;* that is, only if the contraocular stimulus was of roughly the same orientation (tilt) as the target stimulus was the interocular viewing condition comparable to that of monocular viewing. The importance of this additional demonstration for the conclusion of a central locus to the effects rests in the known types of receptive fields of retinal cells (cf. Kuffler

& Nicholls, 1976). The last stage of processing within the retina, that of the ganglion cells, exhibits concentric receptive fields of various sizes. Therefore, purely retinal processing of a stimulus may demonstrate some spatial frequency analysis either by the differential excitation of ganglion cells by stimuli of varying widths or by the combined activity of a large number of ganglion cells with randomly distributed receptive fields (Kelly, 1975). Later, binocularly innervated cortical cells could simply reflect the processing properties of this earlier stage in the system. However, orientational selectivity of these same perceptual effects would not be expected until the involvement of higher centers that combine the output from several such concentric ganglion cells at specific orientations (cf. Hubel & Wiesel, 1962). Hence, the repeated finding in the literature of successful dichoptic (i.e., interocular) viewing is not in itself conclusive evidence for a characteristically or qualitatively different nature to the processing at earlier (retinal) levels in the system prior to the cortical conjunction of monocular signals; but the complementary finding of orientational selectivity renders this same conclusion much more tenable. It should be stressed that the dichoptic procedure alone is not the convincing demonstration.

These examples from the visual literature that deals with hypothesized spatial frequency channels were intended to exemplify an inherent weakness of the dichoptic procedure that results from the hierarchical arrangement of the visual system. With the important exception of orientational selectivity, it does not appear readily apparent how, through the use of the dichoptic procedure alone, a researcher could distinguish between binocular centers that serve largely as relay stations for retinally processed signals and binocular centers that actively process and transform the retinal signals. It is realized that in some respects this argument may strike the reader as somewhat hollow, considering the other available evidence that supports the central locus of these spatial frequency channels (cf. Blake & Levinson, 1977; Breitmeyer & Ganz, 1976). But it should be remembered that the focus of the present argument is not on the specific conclusions of these studies but on their methodology. Julesz (1971) similarly discussed this procedural weakness of the dichoptic procedure, and Kolers's (1972) argument against inferring a necessary cortical locus from the unimpaired dichoptic viewing of some phenomenon rested on the same points (Kolers, Note 1). The importance of this logical error can be demonstrated perhaps more persuasively by reference to an area of research that, like afterimages and aftereffects, may have been retarded by the uncritical and unquestioned use of the dichoptic procedure.

Example 2: Locus of iconic memory. Iconic memory, or short-term visual storage, refers to the persistence exhibited by the visual system following the brief presentation of a target (cf. Neisser, 1967; Sakitt, 1976). It has been argued in the past that the locus of iconic memory must be postretinal because of the demonstrated dichoptic masking of the icon (cf. Dick, 1974; Jacewitz & Lehmann, 1972). However, there is increasing evidence from recent research that the bulk of what has been referred to in the literature as iconic memory involves retinal persistence effects (Long, 1978; Sakitt, 1976; Sakitt & Long, 1978). In her review of the iconic literature, Sakitt (1976) suggested that the peripheral locus of the icon can be reconciled with the results of dichoptic masking experiments if it is assumed that the prolonged signals from the retina are transmitted to the higher levels where binocular interaction occurs. Hence, although the masking itself may take place at a central site of binocular combination, the icons themselves may be due entirely to prolonged photoreceptor activity. As mentioned previously, since the perception of any event occurs not in the eye itself but at higher levels, it is necessarily difficult using the dichoptic procedure to tease out the visual phenomena (e.g., afterimages) that have their predominant impact on the retina (which in turn sends its output to binocularly innervated cortical centers) from the more purely central phenomena that are not contained in the monocular signals alone.

A similar argument can also be raised against the conclusion by Haber and Standing (1969) of the central locus of iconic memory

from results of dichoptic presentation of stimuli in a nonmasking paradigm. In their study, a circular target of variable duration was repeatedly presented at various rates until the subject reported the target to be on continuously. The presentation of the target to alternate eyes on successive flashes (i.e., dichoptic viewing) had no effect on the chosen temporal interval for continuity of perception, as compared with monocular viewing conditions. This lack of difference between monocular and dichoptic viewing of the target was interpreted as evidence for the central locus of the persistence effect. However, in light of the present argument it is claimed that such results actually demonstrate only that the input from the two eyes is combined prior to the perceptual decision about the subjective duration. The results do not indicate whether the persistence occurred prior to or at this point of combination; they show only that the perception of the event occurred after the confluence of the retinal signals.

Value of "correlograms" for localizing processes. The criticisms raised in this section against the inference of a cortical basis to phenomena that can be perceived dichoptically evince serious limitations to the practical value of the typical dichoptic demonstration as an unambiguous psychoanatomical tool. However, it should be noted that these criticisms do not appear to be equally damaging to the related nonphysiological procedures represented by random-dot stereograms. Julesz (1971) painstakingly outlined the value of random-dot stereograms, anaglyphs, and other forms of so-called correlograms in inferring cortical processes for a large range of visual phenomena. The usual criticisms raised against drawing this cortical inference from dichoptic demonstrations are much less applicable to this rather intriguing class of stimuli. Each monocular pattern by itself is drastically inadequate for perception of the given phenomenon and appears to each eye as composed of random dots. It is only in the particular horizontal disparities between portions of the two retinal inputs that the complete visual phenomenon is defined. In Julesz's (1971) words, "Random-dot stereograms do not contain, *even physically* the global information in the left and right retinal projections. It is only the *relation* between the left and right patterns that produces a pattern of the desired kind" (p. 7). Since this comparison between retinal inputs (i.e., disparity detection) can only occur after the locus of conjunction of monocular images, cortical processes must underlie the perception of these phenomena that are portrayed exclusively on the cyclopean retina of the mind's eye.[3]

Summary

The purpose of the present article has been to point out several potential weaknesses that underlie the use of the dichoptic viewing procedure to infer peripheral versus central processes in the perception of a given phenomenon. These problems with the dichoptic procedure were shown to limit the conclusions from either the successful (i.e., unimpaired) or the unsuccessful dichoptic viewing of some visual effect. It was argued that failure in dichoptic viewing, instead of necessarily reflecting the retinal locus of critical processes for the perception of a given phenomenon, could also result from either binocular rivalry effects or the sufficiency of monocularly driven cortical events for a certain percept. On the other hand, the successful dichoptic viewing of a visual phenomenon, instead of indicating the dominant cortical locus of the phenomenon, could result from the phenomenal overlap of the visual fields (such that the observer cannot distinguish actual transfer from continued output from the stimulated eye) and from the relatively

[3] An interesting recent example of the use of such cyclopean stimuli for localizing processes can be found in a study by Fox and Lehmkuhle (Note 2). Dynamic noise stereograms were used to present the brief array of letters in a Sperling (1960) partial-report task. Each monocular pattern alone appeared as randomly moving elements in the display; only in the disparity between certain identical portions in the two monocular inputs were the letters contained (i.e., seen in depth). No iconic memory was found for these purely postretinal letters. Not only is this result consistent with other recent findings that indicate a peripheral locus to iconic memory (e.g., Sakitt & Long, 1978) but it is also opposite to those results, described previously, that were obtained with traditional dichoptic procedures.

late stage of combination of the input from the two eyes. To illustrate each of these arguments, empirical examples were employed to demonstrate the plausibility of each alternate hypothesis to the classic dichoptic interpretation. It is believed that the criticisms raised in this article seriously question the previously uncritical and almost automatic use of the dichoptic viewing procedure for determining the level of the visual system that underlies performance on a given visual task.

Categories for Classifying Language in Psychotherapy

Robert L. Russell
Department of Linguistics
University of North Carolina at Chapel Hill

William B. Stiles
University of North Carolina at Chapel Hill

A review of language analysis systems employed in psychotherapy research suggests a typology based on the combination of three category types with two coding strategies. The types are (a) content categories, (b) intersubjective categories, and (c) extralinguistic categories. They are defined by distinct sets of language features. The coding strategies are (a) the classical coding strategy, in which categories describe the text, and (b) the pragmatic coding strategy, in which categories describe the speaker. A review of research results suggests that the content, intersubjective, and extralinguistic features constitute distinct channels of communication and that (a) the content channel carries information pertaining to the speaker's psychodynamic process and personality structure, (b) the intersubjective channel carries information pertaining to the quality of the speaker's relationship with the other, and (c) the extralinguistic channel carries information pertaining to the speaker's transitory emotional state. System consistency criteria are suggested for use in conjunction with the typology to evaluate categories and category systems.

If the first stage in the scientific study of a phenomenon is naming and classifying, the study of verbal behavior in psychotherapy is mired in its first stage. Reviews of the psychotherapy content analysis literature (Auld & Murray, 1955; Kiesler, 1973; Marsden, 1965, 1971; Meltzoff & Kornreich, 1970) display an ungainly proliferation of categories and systems of categories to describe the verbal behavior of therapist and client. One reviewer (Kiesler, 1973) put it this way:

> Psychotherapy process research has to rank near the forefront of research disciplines characterized as chaotic, prolific, unconnected, and disjointed, with researchers unaware of much of the work that has preceded and the individual investigator tending to start anew completely ignorant of closely related previous work. (p. xvii)

The proliferation of categories and category systems and the disorganization of this area of research reflect the lack of consensus on what are the most significant aspects of verbal interaction. In the absence of a unified theoretical understanding, investigators seem dissatisfied with existing systems, and they continue to search for more illuminating ways to capture the richness of verbal behavior in psychotherapy (Goodman & Dooley, 1976; Kepecs, 1977; Kiesler, 1973; Labov & Fanshel, 1977; Strupp, 1957; Stiles, in press-b). The results of this continuing search—the numerous categories and classification systems—have created a need for an integrated descriptive framework, a framework that would facilitate the comparison and evaluation of alternative categorization schemes (Freedman, Leary, Ossorio, & Coffey, 1951–1952; Reusch & Bateson, 1949; Rice, 1965; Rice & Wagstaff, 1967). The present article addresses this need; that is, it describes an order we see among existing language analysis categories and suggests guidelines for selecting or creating classification systems appropriate for particular research problems.

Our framework is a typology of categories. We use three distinct sets of language features to identify three types of categories.

The authors thank John B. Carroll and Bruce C. Johnson for their comments on a draft of this article.

Requests for reprints should be sent to Robert L. Russell, Department of Linguistics, University of North Carolina, Chapel Hill, North Carolina 27514.

The types we propose subsume the vast majority of the language categories that have been used to study verbal interaction in psychotherapy. In brief, *content* categories, such as *mother* or *death anxiety,* concern denotative or connotative semantic content. *Intersubjective* categories, such as *self-disclosure* or *question,* concern syntactically implied and other relationships between the communicator and recipient. *Extralinguistic* categories, such as *pauses* or *laughing* concern vocal noises, tonal qualities, and temporal patterning of speech, defined independently of semantic content and syntactic structures.

Cutting across the three types are two distinct coding strategies, previously described by Berelson (1952) and by Marsden (1965, 1971). In the *classical* strategy, categories describe characteristics of the text (or some other record of the communication), whereas in the *pragmatic* strategy, categories describe characteristics of the communicator such as his or her internal state, intentions, socioeconomic class, and so on. For example, the category *mother* would be classical if it coded instances of maternal references in the text; the category *death anxiety* would be pragmatic if it coded utterances judged to reflect the communicator's conscious or unconscious concern about death. The classical strategy requires two operational steps from the raw text to inferences about psychological processes: The coder identifies instances of categories in the text, and the researcher later makes inferences based on category frequencies (or indices derived from category frequencies). The classical strategy thus makes explicit the process of inference about the communicator's characteristics. The pragmatic strategy uses only one step; coders make inferences about psychological processes (or other characteristics of the communicator) in the process of coding. These inferences may or may not be based on specified behaviors (e.g., behaviors that instantiate death anxiety may or may not be exhaustively catalogued), but in either case, the specific behaviors are not recorded. Thus the pragmatic strategy permits complex contextual judgments that may be impossible to specify completely (Labov & Fanshel, 1977; Russell, in press), but it obscures the relationships between behaviors and inferred characteristics of the communicator (Marsden, 1971).

The classical–pragmatic distinction has been used for distinguishing whole systems of categories or approaches to psychotherapy process research (Berelson, 1952; Marsden, 1965, 1971), but it is better applied to characterize individual categories: Single systems can (and do) contain both classical and pragmatic categories. Likewise, although the classical–pragmatic distinction has been used primarily for systems that employ content categories, it is useful for intersubjective and extralinguistic categories as well.

Previous efforts at organizing language research in psychotherapy have classified studies or systems by criteria other than category types. Auld and Murray (1955) distinguished methodological studies, descriptive studies of cases, and theoretically guided studies of therapy. Kiesler (1973) distinguished "systems of direct psychotherapy process analysis," which focus on therapist and/or patient behavior, from "systems of indirect psychotherapy analysis," which include indirect process analysis, therapist's conceptions, and patient preferences. Marsden (1965, 1971) partitioned studies into three models, the classical, the pragmatic, and the nonquantitative. As noted above, we have adopted the classical–pragmatic distinction to classify categories. Several other authors have made distinctions that parallel aspects of our typology. Mahl and Schulze (1964), Matarazzo and Wiens (1977), and Phillips, Matarazzo, Matarazzo, Saslow, and Kanfer (1961) have distinguished extralinguistic categories and category systems from all other category and category system types. Phillips et al. recognized two controlling frames of reference: one that "directs attention to the communication aspects of verbal behavior, that is, to some symbolic content of the words spoken, using content analysis to define and quantify its variables" and one that "focuses upon the quantitative temporal characteristics of interview interaction, utilizing measures such as number and duration of utterances, duration of silence, etc." (p. 260). Mahl and Schulze (1964) reviewed just those studies

concerned with the extralinguistic features of speech (e.g., pitch, pauses, rhythm, etc.). Similarly, several investigators (Dollard & Auld, 1959; Murray, 1956; Seeman, 1949; Snyder, 1945, 1963) have implicitly recognized a distinction between content categories and intersubjective categories by constructing systems of content categories for patient verbal behavior and separate systems of intersubjective categories (called *technique* categories by Dollard & Auld, 1959) for therapist verbal responses.

Our 3 × 2 typology is not an exhaustive classification of methods used to analyze verbal interaction in psychotherapy. The typology is not intended to cover ratings of verbal behavior, though ratings clearly cut across our typology. Thus, for example, ratings of client "experiencing" (Klein, Mathieu, Gendlin, & Kiesler, 1970; Rogers, 1958, 1959) or the "immediacy" of therapist or patient responses (Mehrabian, 1972) are not included. Also, the typology is not intended to cover systems that classify language units marked

Table 1
Content Category Systems

Murray (1956); patient content categories pragmatic strategy

Disturbance of free association
Agreement with therapist remarks [intersubjective]
Disagreement with therapist remarks [intersubjective]
Intellectual discussion
General anxiety
Sex
Sex anxiety
Sex frustration
Affection
Affection anxiety
Affection frustration
Dependence
Dependence anxiety
Dependence frustration
Independence and self-assertion
Independence anxiety
Independence frustration
Unspecified anxiety
Unspecified frustration

Stone, Dunphy, Smith, & Ogilvie (1966); Harvard Third Psychosociological Dictionary (partial list); classical strategy

Natural realm; psychological processes; emotions
- Arousal—states of emotional excitement
- Urge—drive states
- Affection—incidents of close . . . relationships
- Pleasure—states of gratification
- Distress—states of despair, guilt, shame, etc.
- Anger—forms of aggressive expression

Thought
- Sense—perceptions and awareness
- Think—cognitive processes
- If—conditional words
- Equal—words denoting similarity
- Not—words denoting negation
- Cause—words denoting a cause–effect relationship

Evaluation
- Good—synonyms for good
- Bad—synonyms for bad
- Ought—words indicating a moral imperative

Dollard & Auld (1959); patient's signs; pragmatic strategy

An internal response-produced stimulus; anxiety, apprehension, distress, tension, or fear
Unconscious anxiety or unconscious sense of guilt
Anxiety is perceptibly reduced
Reduction of unconscious anxiety or guilt
Confirmation
Dependence
Unconscious dependence
Patient is aware of and frightened by his dependent motive
Conscious dependent motive to which unconscious anxiety is attached
Dependent motive is unconscious; anxiety is conscious
Both dependent motive and anxiety are unconscious
Anxiety component is reduced
Unconscious anxiety attached to conscious dependence motive is reduced
Dependence motive is unconscious; conscious anxiety component is reduced
Unconscious anxiety evoked by unconscious dependence motive is reduced

White, Fichtenbaum, & Dollard (1966b); patient's evaluation of self categories; pragmatic strategy

Positive self-evaluation
Anxiety about self, symptom, dissatisfaction
Hostile feelings directed toward others; assertiveness
Hostile feelings directed toward self; self-blame
Nonsexual love and reduced anxiety about family
Anxiety evoked by family members
Sex motive, dating, marital relations
Anxiety evoked by sex motive
Involvement with academic and career motive; social mobility
Anxiety evoked by academic/career motive or social mobility

Table 1 (*continued*)

Kepecs (1977); focal conflict categories; pragmatic strategy	Laffal (1968); Cognitive Conceptual Dictionary (partial list); classical strategy
Positive human relations	Absurd
Hostility out	Agree 1 (sympathy)
Mastery	Agree 2 (agreement)
Assertion	Agree 3 (similarity)
Reactions (reactive motive)	All 1 (whole)
Hostility in	All 2 (much)
Masochism	All 3 (frequent)
Helplessness	Animal
Other defenses	Art
Defensive hostility out	Astronomy 1 (space)
Defensive positive human relations	Astronomy 2 (weather)
Defensive mastery	Back
Adaptive activity; relatively nonconflictual solutions	Bad
	Begin
	Big
Hall & Van de Castle (1966); dream contents (partial list); classical strategy	**Gottschalk & Gleser (1969); Anxiety Content Analysis Scale; pragmatic strategy**
Objects	Death anxiety
Architecture	Mutilation anxiety
Household	Separation anxiety
Food	Guilt anxiety
Implements	Shame anxiety
Travel	Diffuse or nonspecific anxiety
Streets	**Thibaut & Coules (1952); overt aggression categories; pragmatic strategy**
Regions	Direct aggression
Nature	Indirect aggression
Body parts	Affective neutrality
Clothing	Friendly statements
Communication	Self-augmentation
Money	Self-reduction
Miscellaneous	Self-neutral

Note. Discrepant category types are listed in brackets.

for some special syntactic feature such as case (Bieber, Patton, & Fuhriman, 1977; Patton, Fuhriman, & Bieber, 1977). The categories we discuss are mainly nominal variables, so indices of intensity or degree are based on frequencies. We think it best to concentrate on the category types that appear most productive and recur most frequently in psychotherapy process research rather than to attempt to include all possible categories. On the other hand, the typology we propose may also be useful for areas other than psychotherapy research (see Berelson, 1952; for an introduction to applications of language analysis categories to other fields in the social sciences, see Gerbner, Holsti, Krippendorf, Paisley, & Stone, 1969; Holsti, 1968; Pool, 1959).

The category systems shown in Tables 1, 2, and 3 were classified as content, intersubjective, or extralinguistic, respectively, on the basis of predominant category type in the system. Similarly, they were classified as pragmatic or classical on the basis of the predominant coding strategy that was employed to score speech units to the constituent categories.

Content Categories

Content categories describe the semantic content of words or word groups in the text.

Table 2
Intersubjective Category Systems

Stiles (in press-a); verbal response modes

Classical strategy
- Disclosure form
- Question form
- Edification form
- Acknowledgment form
- Advisement form

Matarazzo, Wiens, Matarazzo, & Saslow (1968); interaction chronograph; classical strategy Mean speech duration Mean speech latency Percentage of interruption	Fairbanks & Pronovost (1939); pitch categories; classical strategy Pitch level Pitch range Extent of pitch shifts

Note. Discrepant category types are listed in brackets.

(Examples of content category systems are given in Table 1.) The categories describe manifest or latent content: Denotative meaning and connotative meaning constitute manifest content; referential–contextual, symbolic, or metaphorical meanings constitute latent content. For example, Lasswell (quoted in Kaplan, 1943) wrote, "'I love my husband more than anyone in the whole world' may be taken at its face value; or we may decide that the wife 'doth protest too much.' In the first instance we describe manifest content, and in the second, we interpret according to latent content" (p. 234). Manifest content is identified by the classical coding strategy, in which the coder makes inferences about the characteristics of the communicator.

Classical content categories describe the manifest content of the text; that is, either the dictionary meanings of the words or word groups that occur in the text or the connotative or constituent meanings normally ascribed to them, regardless of the context in which they occur. Thus classical content categories serve "as a conceptual grid to be laid upon a language sample in order to reveal the density of the various concepts in the sample" (Laffal, 1968, p. 280). Classical content categories vary in abstractness. The following is an example of a concrete category (also see Table 1):

Implements: Three subclasses of implements are scored. The first letter of the scoring symbol is I to which a second letter is attached to indicate the subclass.

Tools (Scoring symbol: IT). This subclass includes tools, and machinery parts. Objects that are used in vocational activities are generally included here, although some such as typewriter are scored in the communication class. Examples of the IT subclass are hammer, nail, saw, screwdriver, wrench, pliers, shovel, rake, lawn mower, lathe, X-ray machine, jack, level, and starting button of a machine. Household appliances are scored in the household class and parts of conveyances are scored in the travel class. (Hall & Van de Castle, 1966, p. 46)

At the other end of the range, words or word groups are coded according to their underlying associative or conceptual communality. For example, "We will *start* the project shortly" and "He was *born* on July second" have a common constituent meaning: beginning" (Laffal, 1968, p. 279). The coder in scoring the units *start* and *born* in the category *begin* (see Table 1) employs the classical coding strategy—the semantic feature *beginning* is marked for words like start and born regardless of the context of their use. Scoring depends only on the capability of the coder to recognize semantically similar words or word groups.

Pragmatic content categories describe some characteristic or condition of the communicator. Thus, instead of locating particular words or word groups with similar meanings the coder "now directly scores resistance, tension, adjustment" (Dittes, 1959, p. 329). For example, Murray's (1956; see Table 1) pragmatic content category, *generalized anxiety*, was defined as follows:

Generalized Anxiety: Included all psychological and somatic expressions of anxiety which are not related to a drive nor related to any specific person or object; general "free floating" anxiety and guilt.

a. "I feel panicky about the thought of death."

b. "I tremble and then it would ease off, then I start again . . . in waves."

c. "I feel tense as if there's some force inside of me trying to get out." (p. 27)

Similarly, White, Fichtenbaum, and Dollard's (1966a, 1966b) pragmatic content category *positive self-evaluation* (see Table 1) would be scored for each sentence judged to reflect, by virtue of its content, a favorable attitude toward the speaker. Thus, "I'm getting a broader idea of myself as an entity and full person" (White et al., 1966a, p. 108) is scored to the category *positive self-evaluation*. This scoring procedure typifies the pragmatic scoring strategy employed by those pragmatic content category systems enumerated in Table 1. As the examples above illustrate, many of the pragmatic content categories of interest to researchers of psychotherapy are used as theoretical constructs by clinicians.

A review of published research suggests that content categories have been most successfully employed to investigate internal psychodynamic processes, motives, drive conditions, characterological traits, and changes in these client characteristics in therapy. The focus on internal psychodynamic processes was made explicit by Murray (1954): "We propose to study the content of verbal behavior in psychotherapy with respect to underlying motives and defenses" (p. 305). Murray (1956) also wrote, "The categories of the content analyses were defined in terms of motivation and conflict, influenced by psychoanalytic and learning theories, and formulated in such a way as to be most relevant to an eventual understanding of the underlying processes of psychotherapy" (p. 23). Auld and Dollard (1966) enumerated the key psychological phenomena that they felt were amenable to investigation with content categories: resistance, transference, unconscious motive, inhibition, dependence, hostility, and interpretation. Dollard and Mowrer (1947), Raimy (1948), Kauffman and Raimy (1949, Murray, Auld, and White (1954), Leary and Gill (1959), Freedman et al. (1951–1952), Lennard and Bernstein (1960, 1969), Auld and White (1959), White et al. (1966a, 1966b), Hall and Van de Castle (1966), and Thibaut and Coules (1952) have carried out investigations that embrace similar assumptions.

As an example of the use of content categories to investigate psychodynamic processes, Murray (1954) found that the frequency of hostility statements in psychotherapy increased as the frequency of defensive statements decreased; he interpreted this as evidence that the client's anxiety had decreased as therapy progressed. Thibaut and Coules (1952), focusing on the relative frequency of hostility statements, reported that residual hostility lessened for subjects who directly communicated their hostile feelings after being provoked. White et al. (1966a) were able to determine that "the therapist focused more than the patient did during the active period of therapy on the areas of sex and evaluation of self" (p. 47) by the high proportion of statements scored to these content categories. By considering sex and evaluation of self as the therapist's target area, the authors were

able to report that the therapist had apparently been successful: The scored content of the patient's talk about these areas increased from the first to last quarter of therapy and was judged to be adaptive. Lennard and Bernstein (1960) reported that in the data collected from four therapists and two patients who interacted in a total of 500 sessions, "the therapists as a group led the patients slightly in the proportion of communication dealing with affect" (p. 85). In comparing the early with the later sessions, they found that "the proportion of both therapist and patient references devoted to feelings increased—almost doubled—for the sample as a whole" (p. 85).

Content categories also reflect personality variables, as well as trends or focal points in the communicated content. Sarason, Ganzer, and Singer (1972) found that high- and low-defensive subjects used different content categories to describe themselves, after having listened to models that differed in self-disclosure style. Kepecs (1977) used content categories to locate the focal conflict of the client. Auld and White (1959) found that experienced therapists are more likely to intervene than are apprentice therapists following a patient's utterance scored as resistance. They also reported that the patient's talk seemed to hang together: Categories on a specific topic were more likely to follow one another than to be followed by a category on a different topic. Although content categories have been used most consistently to investigate internal psychodynamics and characterological traits, one group of researchers (Gottschalk & Frank, 1967; Gottschalk & Gleser, 1969; Gottschalk, Winget, & Gleser, 1969) have concluded that "the relative magnitude of an affect can be validly estimated from the typescript of the speech of an individual using solely content variables and not including paralanguage variables" (Gottschalk & Gleser, 1969, p. 96). A number of studies have been carried out that directly or indirectly address this issue (Cook, 1969; Gottschalk & Frank, 1967; Hart & Brown, 1974; Mahl, 1956, 1959; Markel, Meisels, & Houck, 1964; Markel & Roblin, 1965; Mehrabian & Ferris, 1967). Though the empirical findings are somewhat equivocal, Mahl's (1956) theoretical assessment that "the most valid measures [of transitory states] will be based on the expressive [i.e., extralinguistic] aspects of speech rather than on the manifest content measures" (p. 13) is still most compelling, empirically and theoretically (see Mahl, 1959, for a theoretical discussion of this issue; see Cook, 1969; Markel & Roblin, 1965, for some empirical evidence).

Intersubjective Categories

Intersubjective categories are descriptive of syntactically implied and other relationships between the communicator and recipient. For example, *self-disclosure* implies that the communicator reveals something to the recipient, *question* implies that the communicator seeks information from the recipient, and so forth. (Examples of intersubjective category systems are given in Table 2.) In contrast to content categories, intersubjective categories can typically be defined without reference to the semantic content (or extralinguistic features) of the communication.

Many intersubjective categories can be defined by syntactic features alone (Goodman & Dooley, 1976; Stiles, 1978, in press-b). For example, *question* has a well-attested set of syntactic features associated with it; *self-disclosure* can be defined as a first-person declarative sentence. Since these syntactic features are characteristics of the text, speech units are scored to such categories by means of the classical coding strategy. For example, in Stiles's (1978, in press-a, in press-b) classical intersubjective system (see Table 2), sentences such as "I'd really like to talk about my feelings of being an experimental subject" and "I can't stand needles" would be scored to the category *disclosure form* because of their first-person subjects.

The intersubjective categories used in psychotherapy research are more often descriptive of interpersonal intentions, which may or may not be expressed using the corresponding syntactic form. For example, an utterance identified as a question by syntactic criteria may express the interpersonal intention "asks for information," but it may also express the

interpersonal intention "gives suggestion," as in "Don't you think you should lock the door?"

In Goodman and Dooley's (1976) system, such utterances as "I had the same problem and solved it with . . . " or "Do you think it would work better if you tried . . . " (p. 109) would be scored to the pragmatic content category *advisement* (see Table 2). To judge whether a communicator is giving a suggestion or is asking for information, the coder must infer the communicator's intent and thus employs the pragmatic coding strategy. Pragmatic intersubjective categories are used frequently in interaction research, though they require the coder to make more complicated inferences than their classical counterparts. For instance, *confrontation* is defined by Barnabei, Cormier, and Nye (1974) as "a response indicating some sort of discrepancy in the client's message . . . a 'you said but look' condition" (p. 356). Or, similarly, *direct guidance* (see Table 2) is defined by Strupp and Wallach (1965) as "suggestions for activity either within or outside of the therapeutic framework; giving information, stating an opinion, answering direction questions, speaking as an authority" (p. 118).

In published research, intersubjective categories have been most consistently and successfully employed to measure psychotherapeutic technique, interpersonal roles and relationships in therapy, and therapy process. Intersubjective categories have long been used to describe and teach psychotherapeutic technique. Freud (1912/1958) explicitly argued in favor of using interpretation while he condemned suggestion and disclosure. Rogers (1942, 1951, 1957) advocated reflection (or *restatement* or *clarification*) as a technique. More recently, comprehensive systems of intersubjective categories have been developed to aid in training counselors and therapists (e.g., Goodman & Dooley, 1976; Ivey, 1971). Research evaluating these systems has demonstrated their efficacy in training new professionals (e.g., Moreland, Ivey, & Phillips, 1973).

In view of the different technical prescriptions of the various schools of therapy, it is not surprising that intersubjective categories consistently differentiate the therapeutic interventions made by practitioners of those schools (Auerbach, 1963; Cartwright, 1966; Staples, Sloane, & Whipple, 1976; Strupp, 1955, 1957; Stiles, in press-b). In addition, several studies have used intersubjective categories to describe a single type of psychotherapy (Porter, 1943; Seeman, 1949; Snyder, 1945; Strupp, 1958). In these studies, client-centered, psychoanalytic, existential, gestalt, and behavior therapists have been shown to use characteristic but different profiles of intersubjective categories. Similarly, therapists' style of participation, as well as that of clients, has been related to their choice of intersubjective categories (Rice, 1965, 1973; Rice & Wagstaff, 1967; Segal, 1970). Intersubjective categories have also been employed to characterize the verbal interaction of schizophrenic families. Lennard and Bernstein (1969) found that in a schizophrenic family the child's presentations of self are disconfirmed by the mother and "her presentations (of him) are disconfirmed by him" (p. 125). Bandura, Lipsher, and Miller (1960), Frank and Sweetland (1962), Murray (1956), Rottschafer and Renzaglia (1962), and Winder, Farrukh, Bandura, and Rau (1962) showed that differential utilization of certain intersubjective categories resulted in alteration of the content of the client's speech.

Extralinguistic Categories

Extralinguistic categories are descriptive of vocal noises that do not have the structure of language: modifications such as pitch, resonance, amplitude, and so on of language and other vocal noises, and temporal patternings associated with language behavior. (Examples of extralinguistic category systems are given in Table 3.) Extralinguistic categories are defined without reference to either semantic content or syntactic structure.

Vocal noises that do not have the structure of language have been termed *vocalizations* (Trager, 1958). The following six extralinguistic categories are examples of vocalizations (1–3 from Mahl, 1956; 4–6 from Dibner, 1956, 1958; see Table 3).

1. Whenever the definite *ah* sound occurs, it is scored.

2. An *intruding incoherent sound* is a sound that is absolutely incoherent as a word to the listener.

3. *Stutter.*

4. *Sighing* (or deep breath).

5. *Laughing* includes any kind of laugh or chuckle.

6. *Blocking* occurs when there is groping for the proper expression, indicating unusual hesitation.

Modifications of language and other vocal noises have been termed *qualifiers* (Trager, 1958). Pitch, rhythm, resonance, loudness, intonation, and so on are typical modifications of the noises people emit.

The following three categories (Fairbanks & Pronovost, 1939) illustrate how one specific modification (i.e., pitch) might be delineated for use in analyzing patterns of speech (see Table 3).

1. *Pitch level* is median frequency in cycles per second.

2. *Pitch range* is the highest minus the lowest pitch in cycles per second.

3. *Extent of pitch shifts* is the change in pitch between the last pitch measured in a given phonation and the first pitch measured in the phonation that follows.

Utterance duration, utterance latency, rate of speech production, and so on are observable characteristics of speech production and can be termed *temporal patterning in speech.* An example is Matarazzo, Wiens, Matarazzo, and Saslow's (1968) unit of latency silence (see Table 3), defined as "the duration of time from the moment one person in the dyad terminates an utterance until the second person begins his next comment" (p. 355).

Most extralinguistic categories have used the classical strategy; indeed, investigators who use extralinguistic systems have prided themselves on the objectivity of their systems (e.g., Mahl, 1959; Matarazzo et al., 1968; Phillips et al., 1961; Saslow & Matarazzo, 1959). However, there is no inherent barrier to coding communicator characteristics directly from extralinguistic cues, that is to using the pragmatic strategy for extralinguistic categories. An example of a pragmatic extralinguistic category is Bales's (1950, 1970) category *shows tension* (see Table 2):

> Several varieties of acts are scored in this category, not all of which may seem similar on a superficial level. Laughter, in particular, may seem quite different from signs of anxious emotionality. Signs of anxious emotionality indicate a conflict between acting and withholding action. Minor outbreaks of reactive anxiety may first be mentioned, such as appearing startled, disconcerted, alarmed, dismayed, perturbed, or concerned. Hesitation, speechlessness, flurry, fluster, confusion, trembling, blushing, flushing, stammering, sweating, blocking-up, gulping, swallowing, or wetting the lips persistently may also be included. (Bales, 1970, p. 124)

Judging from published research, extralinguistic categories have been used most successfully to investigate transitory motivational and emotional states. The association of speech disturbances with states of anxiety and tension has been long established by investigators using a variety of speech disturbance categories and indices of anxiety (Dibner, 1956, 1958; Eldred & Price, 1958; Lasswell, 1935; Mahl, 1956, 1959; Panek & Martin, 1959). Dibner (1956), for example, found that situational anxiety produced by the use of ambiguous techniques by the interviewer was associated with speech disturbances in the patient. Kasl and Mahl (1965), Mahl (1959), and Cook (1969) have shown that speech disturbance categories are more sensitive to momentary states of anxiety than to trait anxiety. For example, Cook found that two measures of trait anxiety were not related to the non-ah speech disturbance categories (the measures of anxiety were the Taylor Manifest Anxiety Scale and the McReynolds Assimilation Scale), while transient anxiety was related.

Extralinguistic categories have also been found to be sensitive to other transitory emotional states besides anxiety (Boomer, 1965; Eldred & Price, 1958; Hargreaves, Starkweather, & Blacker, 1965). In fact, the association of affective states with extralinguistic cues is apparently well enough appreciated by most people that the cues can be used to communicate specific emotions. For instance, Fairbanks and Pronovost (1939) have shown that the communication of five

different emotions (i.e., contempt, anger, fear, grief, and indifference) can be reliably distinguished by measures of mean pitch levels, mean pitch ranges, and the mean extent of pitch shifts and that these specific emotions can be reliably identified by listeners. Similarly, Beier and Zautra (1972) have shown that the affective information communicated extralinguistically can even be understood, at least in part, by people of different cultures.

In more recent years, research with extralinguistic categories has identified more subtle—though equally important—transitory states. Boomer and Dittman (1963) suggested that filled pauses might serve as an index of self-monitoring by clients in psychotherapy, and the same function for unfilled pauses has been suggested (Rochester, 1973). Manaugh, Wiens, and Matarazzo (1970) found that subjects instructed to lie to their interviewer showed significant differences in their mean duration of utterance as compared with subjects who were not told to lie. Another group of researchers (Butler, Rice, & Wagstaff, 1962; Duncan, Rice & Butler, 1968; Rice, 1965; Rice & Wagstaff, 1967; Wexler & Butler, 1976) have tentatively identified several constellations of extralinguistic features that have differential associations with therapy outcome, counselor and client participation, and the "good" hour.

Extralinguistic features of speech have also been used to investigate personality traits or characterological makeup. However, reviewers of this field of inquiry have been skeptical of the appropriateness of using extralinguistic categories as a basis for making inferences about personality types. For instance, Starkweather (1961) maintained that "despite the frequent reports of success in identifying personality traits from vocal cues, the numerous [reported] failures . . . leave the writer pessimistic concerning the utility of inferring such traits from non-verbal [but vocal] stimuli" (p. 65). Although recent work in this area has shown some success, parallel studies frequently do not confirm the findings. For example, the personality dimensions of assertiveness/dominance and extraversion/sociability have been identified with high interjudge agreement from extralinguistic features (Markel et al., 1964; Markel & Roblin, 1965; Sherer, 1972). However, in related studies, patterns inconsistent with the above results were obtained (e.g., Hart & Brown, 1974).

Recommendations

Criteria for constructing and evaluating category systems have been proposed by others (Butler et al., 1962; Goodman & Dooley, 1976; Heyns & Zander, 1953; Holsti, 1968, 1969; Lazarsfeld & Barton, 1951; Weick, 1968). These criteria fall into two classes, those that deal with the practicability of systems and those that deal with the internal consistency of categories and category systems. Although our typology can serve as a useful guide in identifying or constructing categories and category systems that conform to the criteria of both classes, we limit our discussion to (a) suggesting means by which a researcher can attain internally consistent categories and category systems and (b) pointing out some common methodological problems. (See Goodman & Dooley, 1976, for a recent set of practicability criteria.)

System Consistency Criteria

1. The categories within the system should be mutually exclusive, that is, "there should be one and only one place to put an item within a given classification system" (Lazarsfeld & Barton, 1951, p. 151; see also Butler et al., 1962; Holsti, 1969).

2. The categories within the system should be exhaustive: All relevant items in the sample must be capable of being placed into a category (Holsti, 1969).

3. The categories within the system should be derivable from a single classification principle; that is, "conceptually different levels of analysis must be kept separate" (Holsti, 1969, p. 100). "When an object is classified at the same time from more than one aspect, each aspect must have its own separate set of categories" (Lazarsfeld & Barton, 1951, p. 157); that is, if one is interested in classifying items in terms of a number of different aspects simultaneously, a fully multidimensional classification must be set up.

Our typology suggests two recommendations for meeting the system consistency criteria: (a) Categories should be pure types, that is, content, intersubjective, or extralinguistic combined with either the classical or the pragmatic strategy, rather than conjunctive or disjunctive mixtures, and (b) categories within a system (or subsystem) should be of the same type.

Thus, we identify two types of problematic coding schemes: categories that are conjunctive or disjunctive mixtures and systems that mix together category types. For example, the Strupp (1957) category *structuring* (see Table 2) is scored when the therapist is judged to be structuring the therapeutic situation (i.e., an intersubjective category type) or when the therapist is discussing theory (i.e., a content category type). A mixed system is one in which the categories are of more than one type. For example, Heyns and Zander (1953, p. 391) pointed out that Bales's (1950) interaction process analysis system (see Table 2) contains more than one type of category: "Category 3, Shows Solidarity and Category 2, Shows Tension Release seem to be descriptions of interaction along affective dimensions" (and are defined with reference to extralinguistic features); "Category 5, Gives Opinion, Category 6, Gives Orientation and Category 4, Gives Suggestion refer to intellectual problem-solving activity of the group" (and are defined with reference to intersubjective features).

Following the recommendations suggested by the typology does not constrain the researcher from employing a variety of category and category system construction strategies, but does help facilitate the systematic organization of such strategies. For instance, the sentence "Did m-mother really leave?" can be coded to any of the three category types, using either the classical or the pragmatic strategy. It might be scored to the classical content category *mother*, the pragmatic content category *separation anxiety*, the classical intersubjective category *question*, the pragmatic intersubjective category *seeking reassurance*, the classical extralinguistic category *stutter*, and the pragmatic extralinguistic category *nervousness*. Insisting that a system contain only one type of category (i.e., recommendation b) and that categories should be pure types (i.e., recommendation a) does not guarantee that categories within a system will be mutually exclusive (i.e., system consistency criterion 1) or that each of the categories will be derivable from a single classification principle (i.e., system consistency criterion 3), but permitting a system to contain more than one category type or mixed categories virtully guarantees that the system will not be mutually exclusive or derivable from a single principle.

Application of the typology makes category identification explicit and reasonably simple, permitting researchers to separate conceptually and empirically different levels of analysis that heretofore have too often been lumped together. Thus, logically sound category systems, consisting of pure category types, can be constructed with reference to the three sets of features, content, intersubjective, and extralinguistic. By keeping these dimensions separate, researchers interested in more than one set of features can build truly multidimensional systems.

Our view suggests that the content, intersubjective, and extralinguistic categories correspond to distinct channels of verbal communication, which convey different types of psychological information. Information concerning the speaker's personality structure and dynamics is carried primarily in the content channel; information concerning the nature of the speaker's current relationship to the other person is carried primarily in the intersubjective channel; and information concerning the speaker's transitory emotional state is carried primarily in the extralinguistic channel. Although these associations are not exclusive, they are strong enough to recommend that investigators interested in one type of information would be wise to select a system that codes the corresponding channel.

The division of the study of language behavior in psychotherapy into three areas reflects not only trends in the empirical studies reviewed and theoretical and methodological considerations but also historical and philosophical views at large. For example, Johnson (1976), influenced by Kuhn's (1970) analysis of the structure of scientific enterprises, argued "that two of the major under-

lying paradigms in present day psychology are the behavioristic paradigm and the Freudian paradigm" (p. 4). He pointed out that those psychotherapy process researchers "who have been influenced by Freud have stressed the importance of the content of the interview" (p. 4), while those who have been heavily influenced by behaviorism (or more specifically, positivism) have "focused on clearly denotable subject behaviors" (p. 5), as are measured by the Interaction Chronograph (Matarazzo et al., 1968). A third paradigm in psychotherapy process research has grown out of the search for variables with "systematic interpersonal reference" (Freedman et al., 1951–1952, p. 143). Researchers influenced by this interpersonal orientation describe relationships in terms of the sorts of information conveyed through intersubjective categories.

If from one perspective process studies of psychotherapy have appeared chaotic, repetitive, and so forth, we have found that the typology provides a descriptive framework within which many of the unresolved and seemingly unrelated problems tend to cluster and come into clearer focus. We hope that this framework will provide some of the impetus needed to begin to move psychotherapy process research out of its first stage.

Intraclass Correlations: Uses in Assessing Rater Reliability

Patrick E. Shrout and Joseph L. Fleiss
Division of Biostatistics
Columbia University, School of Public Health

Reliability coefficients often take the form of intraclass correlation coefficients. In this article, guidelines are given for choosing among six different forms of the intraclass correlation for reliability studies in which n targets are rated by k judges. Relevant to the choice of the coefficient are the appropriate statistical model for the reliability study and the applications to be made of the reliability results. Confidence intervals for each of the forms are reviewed.

Most measurements in the behavioral sciences involve measurement error, but judgments made by humans are especially plagued by this problem. Since measurement error can seriously affect statistical analysis and interpretation, it is important to assess the amount of such error by calculating a reliability index. Many of the reliability indices available can be viewed as versions of the intraclass correlation, typically a ratio of the variance of interest over the sum of the variance of interest plus error (Bartko, 1966; Ebel, 1951; Haggard, 1958).

There are numerous versions of the intraclass correlation coefficient (*ICC*) that can give quite different results when applied to the same data. Unfortunately, many researchers are not aware of the differences between the forms, and those who are often fail to report which form they used. Each form is appropriate for specific situations defined by the experimental design and the conceptual intent of the study. Unfortunately, most textbooks (e.g., Hayes, 1973; Snedecor & Cochran, 1967; Winer, 1971) describe only one or two forms of the several possible. Making the plight of the researchers worse, some of the older references (e.g., Haggard, 1958) contain mistakes that have been corrected in a variety of forums (Bartko, 1966; Feldt, 1965).

In this article, we attempt to give a set of guidelines for researchers who have use for intraclass correlations. Six forms of the *ICC* are discussed here. We discuss these forms in the context of a reliability study of the ratings of several judges. This context is a special case of the one-facet generalizability study (G study) discussed by Cronbach, Gleser, Nanda, and Rajaratnam (1972). The results we present are applicable to other one-facet studies, but we find the case of judges most compelling.

The guidelines for choosing the appropriate form of the *ICC* call for three decisions: (a) Is a one-way or two-way analysis of variance (ANOVA) appropriate for the analysis of the reliability study? (b) Are differences between the judges' mean ratings relevant to the reliability of interest? (c) Is the unit of analysis an individual rating or the mean of several ratings? The first and second decisions pertain to the appropriate statistical model for the reliability study, and the second and the third to the potential use of its results.

Models for Reliability Studies

In a typical interrater reliability study, each of a random sample of n targets is rated independently by k judges. Three different

Table 1
Analysis of Variance and Mean Square Expectations for One- and Two-Way Random Effects and Two-Way Mixed Model Designs

Source of variation	df	MS	*EMS*: One-way random effects for Case 1	Two-way random effects for Case 2	Two-way mixed model for Case 3[a]
Between targets	$n - 1$	BMS	$k\sigma_T^2 + \sigma_W^2$	$k\sigma_T^2 + \sigma_I^2 + \sigma_E^2$	$k\sigma_T^2 + \sigma_E^2$
Within target	$n(k - 1)$	WMS	σ_W^2	$\sigma_J^2 + \sigma_I^2 + \sigma_E^2$	$\theta_J^2 + f\sigma_I^2 + \sigma_E^2$
Between judges	$(k - 1)$	JMS	—	$n\sigma_J^2 + \sigma_I^2 + \sigma_E^2$	$n\theta_J^2 + f\sigma_I^2 + \sigma_E^2$
Residual	$(n - 1)(k - 1)$	EMS	—	$\sigma_I^2 + \sigma_E^2$	$f\sigma_I^2 + \sigma_E^2$

[a] $f = k/(k - 1)$ for the last three entries in this column.

cases of this kind of study can be defined:

1. Each target is rated by a different set of k judges, randomly selected from a larger population of judges.

2. A random sample of k judges is selected from a larger population, and each judge rates each target, that is, each judge rates n targets altogether.

3. Each target is rated by each of the same k judges, who are the only judges of interest.

Each kind of study requires a separately specified mathematical model to describe its results. The models each specify the decomposition of a rating made by the ith judge on the jth target in terms of various effects. Among the possible effects are those for the ith judge, for the jth target, for the interaction between judge and target, for the constant level of ratings, and for a random error component. Depending on the way the study is designed, different ones of these effects are estimable, different assumptions must be made about the estimable effects, and the structure of the corresponding ANOVA will be different. The various models that result from the above cases correspond to the standard ANOVA models, as discussed in a text such as Hayes (1973). We review these models briefly below.

Under Case 1, the effects due to judges, to the interaction between judge and target, and to random error are not separable. Let x_{ij} denote the ith rating $(i = 1, \ldots, k)$ on the jth target $(j = 1, \ldots, n)$. For Case 1, we assume the following linear model for x_{ij}:

$$x_{ij} = \mu + b_j + w_{ij}. \quad (1)$$

In this equation, the component μ is the overall population mean of the ratings; b_j is the difference from μ of the jth target's so-called true score (i.e., the mean across many repeated ratings on the jth target); and w_{ij} is a residual component equal to the sum of the inseparable effects of the judge, the Judge × Target interaction, and the error term. The component b_j is assumed to vary normally with a mean of zero and a variance of σ_T^2 and to be independent of all other components in the model. It is also assumed that the w_{ij} terms are distributed independently and normally with a mean of zero and a variance of σ_W^2. The expected mean squares in the ANOVA table appropriate to this kind of study (technically a one-way random effects layout) appear under Case 1 in Table 1.

The models for Case 2 and Case 3 differ from the model for Case 1 in that the components of w_{ij} are further specified. Since the same k judges rate all n targets, the component representing the ith judge's effect may be estimated. The equation

$$x_{ij} = \mu + a_i + b_j + (ab)_{ij} + e_{ij} \quad (2)$$

is appropriate for both Case 2 and Case 3. In Equation 2, the terms x_{ij}, μ, and b_j are defined as in Equation 1; a_i is the difference from μ of the mean of the ith judge's ratings; $(ab)_{ij}$ is the degree to which the ith judge departs from his or her usual rating tendencies when confronted by the jth target; and e_{ij} is the random error in the ith judge's scoring of the jth target. In both Cases 2 and 3 the target component b_j is assumed to vary normally with a mean of zero and variance σ_T^2 (as in

Case 1), and the error terms e_{ij} are assumed to be independently and normally distributed with a mean of zero and variance σ_e^2.

Case 2 differs from Case 3, however, with regard to the assumptions made concerning a_i and $(ab)_{ij}$ in Equation 2. Under Case 2, a_i is a random variable that is assumed to be normally distributed with a mean of zero and variance σ_J^2; under Case 3, it is a fixed effect subject to the constraint $\Sigma a_i = 0$. The parameter corresponding to σ_J^2 is $\theta_J^2 = \Sigma a_i^2/(k-1)$.

In the absence of repeated ratings by each judge on each target, the components $(ab)_{ij}$ and e_{ij} cannot be estimated separately. Nevertheless, they must be kept separate in Equation 2 because the properties of the interaction are different in the two cases being considered. Under Case 2, all the components $(ab)_{ij}$, where $i = 1, \ldots, k; j = 1, \ldots, n$, can be assumed to be mutually independent with a mean of zero and variance σ_I^2. Under Case 3, however, independence can only be assumed for interaction components that involve different targets. For the same target, say the jth, the components are assumed to satisfy the constraint

$$\sum_{i=1}^{k} (ab)_{ij} = 0.$$

A consequence of this constraint is that any two interaction components for the same target, say $(ab)_{ij}$ and $(ab)_{i'j}$, are *negatively* correlated (see, e.g., Scheffé, 1959, section 8.1). The reason is that because of the above constraint,

$$0 = \operatorname{var}\left[\sum_{i=1}^{k} (ab)_{ij}\right] = k \operatorname{var}\left[(ab)_{ij}\right] + k(k-1)\operatorname{cov}\left[(ab)_{ij}, (ab)_{i'j}\right] = k\sigma_I^2 + k(k-1)c,$$

say, where c is the common covariance between interaction effects on the same target. Thus

$$c = \frac{-\sigma_I^2}{k-1}. \qquad (3)$$

The expected mean squares in the ANOVA for Case 2 (technically a two-way random effects layout) and Case 3 (technically a two-way mixed effects layout) are shown in the final two columns of Table 1. The differences are that the component of variance due to the interaction (σ_I^2) contributes additively to each expectation under Case 2, whereas under Case 3, it does not contribute to the expected mean square between targets, and it contributes additively to the other expectations after multiplication by the factor $f = k/(k-1)$.

In the remainder of this article, various intraclass correlation coefficients are defined and estimated. A rigorous definition is adopted for the *ICC*, namely, that the *ICC* is the correlation between one measurement (either a single rating or a mean of several ratings) on a target and another measurement obtained on that target. The *ICC* is thus a bona fide correlation coefficient that, as is shown below, is often but not necessarily identical to the component of variance due to targets divided by the sum of it and other variance components. In fact, under Case 3, it is possible for the population value of the *ICC* to be negative (a phenomenon pointed out some years ago by Sitgreaves [1960]).

Decision 1: A One- or Two-Way Analysis of Variance

In selecting the appropriate form of the *ICC*, the first step is the specification of the appropriate statistical model for the reliability study (or G study). Whether one analyzes the data using a one-way or a two-way ANOVA depends on whether the study is designed according to Case 1, as described earlier, or according to Case 2 or 3. Under Case 1, the one-way ANOVA yields a between-targets mean square (*BMS*) and a within-target mean square (*WMS*).

From the expectations of the mean squares shown for Case 1 in Table 1, one can see that *WMS* is as unbiased estimate of σ_W^2; in addition, it is possible to get an unbiased estimate of the target variance σ_T^2 by subtracting *WMS* from *BMS* and dividing the difference by the number of judges per target. Since the w_{ij} terms in the model for Case 1 (see Equation 1) are assumed to be independent, one can see that σ_T^2 is equal to the covariance between two ratings on a target. Using this information, one can write a formula to estimate ρ, the population value of the *ICC* for Case 1. Because the covariance of the ratings is a variance term, the index

in this case takes the form of a variance ratio:

$$\rho = \sigma_T^2/(\sigma_T^2 + \sigma_W^2).$$

The estimate, then, takes the form

$$ICC(1, 1) = \frac{BMS - WMS}{BMS + (k-1)WMS},$$

where k is the number of judges rating each target. It should be borne in mind that while $ICC(1, 1)$ is a consistent estimate of ρ, it is biased (cf. Olkin & Pratt, 1958).

If the reliability study has the design of Case 2 or 3, a Target $\times$ Judges two-way ANOVA is the appropriate mode of analysis. This analysis partitions the within-target sum of squares into a between-judges sum of squares and a residual sum of squares. The corresponding mean squares in Table 1 are denoted JMS and EMS.

It is crucial to note that the expectation of BMS under Cases 2 and 3 is different from that under Case 1, even though the computation of this term is the same. Because the effect of judges is the same for all targets under Cases 2 and 3, interjudge variability does not affect the expectation of BMS. An important practical implication is that for a given population of targets, the observed value of BMS in a Case 1 design tends to be larger than that in a Case 2 or Case 3 design.

There are important differences between the models for Case 2 and Case 3. Consider Case 2 first. From Table 1 one can see that an estimate of the target variance σ_T^2 can be obtained by subtracting EMS from BMS and dividing the difference by k. Under the assumptions of Case 2 that judges are randomly sampled, the covariance between two ratings on a target is again σ_T^2, and the expression for

Table 2
Four Ratings on Six Targets

Within target	18	6.26
Between judges	3	32.49
Residual	15	1.02

the parameter ρ is again a variance ratio:

$$\rho = \sigma_T^2/(\sigma_T^2 + \sigma_J^2 + \sigma_I^2 + \sigma_E^2).$$

It is estimated by

$$ICC(2, 1) = \frac{BMS - EMS}{BMS + (k-1)EMS + k(JMS - EMS)/n},$$

where n is the number of targets. To our knowledge, Rajaratnam (1960) and Bartko (1966) were the first to give this form. Like $ICC(1, 1)$, $ICC(2, 1)$ is a biased but consistent estimator of ρ.

As we have discussed, the statistical model for Case 3 differs from Case 2 because of the assumption that judges are fixed. As the reader can verify from Table 1, one implication of this is that no unbiased estimator of σ_T^2 is available when $\sigma_I^2 > 0$. On the other hand, under Case 3, σ_T^2 is no longer equal to the covariance between ratings on a target, because of the correlated interaction terms in Equation 2. Because the interaction terms on the same target are correlated, as shown in Equation 3, the actual covariance is equal to $\sigma_T^2 - \sigma_I^2/(k-1)$. Another implication of the Case 3 assumption is that the total variance is equal to $\sigma_T^2 + \sigma_I^2 + \sigma_E^2$, and thus the correlation is

$$\rho = \frac{\sigma_T^2 - \sigma_I^2/(k-1)}{\sigma_T^2 + \sigma_I^2 + \sigma_E^2}.$$

This is estimated consistently but with bias by

$$ICC(3, 1) = \frac{BMS - EMS}{BMS + (k-1)EMS}.$$

As is discussed in the next section, the interpretation of $ICC(3, 1)$ is quite different from that of $ICC(2, 1)$.

It is not likely that $ICC(2, 1)$ or $ICC(3, 1)$ will ever be erroneously used in a Case 1 study, since the appropriate mean squares would not be available. The misuse of $ICC(1, 1)$ on data

Table 4
Correlation Estimates From Six Intraclass Correlation Forms

Form	Estimate
ICC (1, 1)	.17
ICC (2, 1)	.29
ICC (3, 1)	.71
ICC (1, 4)	.44
ICC (2, 4)	.62
ICC (3, 4)	.91

from Case 2 or Case 3 studies is more likely. A consequence of this mistake is the underestimation of the true correlation ρ. For the same set of data, $ICC(1, 1)$ will, on the average, give smaller values than $ICC(2, 1)$ or ICC (3,1).

To help the reader appreciate the differences among these coefficients and also among the two coefficients to be discussed later, we apply the various forms to an example. Table 2 gives four ratings on six targets, Table 3 shows the ANOVA table, and Table 4 gives the calculated correlation estimates for various cases.

Given the choice of the appropriate index, tests of the null hypothesis—that $\rho = 0$—can be made, and confidence intervals around the parameter can be computed. When using $ICC(1, 1)$, the test that ρ is different from zero is provided by calculating $F_o = BMS/WMS$ and testing it on $(n-1)$ and $n(k-1)$ degrees of freedom. A confidence interval for ρ can be computed as follows: Let $F_{1-p}(i, j)$ denote the $(1-p)\cdot 100$th percentile of the F distribution with i and j degrees of freedom, and define

$$F_U = F_o \cdot F_{1-\frac{1}{2}\alpha}[n(k-1), (n-1)] \quad (4)$$

and

$$F_L = F_o / F_{1-\frac{1}{2}\alpha}[(n-1), n(k-1)]. \quad (5)$$

Then

$$\frac{F_L - 1}{F_L + (k-1)} < \rho < \frac{F_U - 1}{F_U + (k-1)} \quad (6)$$

is a $(1-\alpha)\cdot 100\%$ confidence interval for ρ.

When $ICC(2, 1)$ is appropriate, the significance test is again an F test, using $F_o = BMS/EMS$ on $(n-1)$ and $(k-1)(n-1)$ degrees of freedom. The confidence interval for $ICC(2, 1)$ is more complicated than that for $ICC(1, 1)$, since the index is a function of three independent mean squares. Following Satterthwaite (1946), Fleiss and Shrout (1978) have derived an approximate confidence interval. Let

$$\nu = \frac{(k-1)(n-1)\{k\hat{\rho}F_J + n[1 + (k-1)\hat{\rho}] - k\hat{\rho}\}^2}{(n-1)k^2\hat{\rho}^2F_J^2 + \{n[1 + (k-1)\hat{\rho}] - k\hat{\rho}\}^2},$$

where $F_J = JMS/EMS$ and $\hat{\rho} = ICC(2, 1)$. If we define $F^* = F_{1-\frac{1}{2}\alpha}[(n-1), \nu]$ and $F_* = F_{1-\frac{1}{2}\alpha}[\nu, (n-1)]$, then

$$\frac{n(BMS - F^*EMS)}{F^*[kJMS + (kn-k-n)EMS] + nBMS} < \rho < \frac{n(F_*BMS - EMS)}{kJMS + (kn-k-n)EMS + nF_*BMS} \quad (7)$$

gives an approximate $(1-\alpha)\cdot 100\%$ confidence interval around ρ.

Finally, when appropriate, $ICC(3, 1)$ is tested with $F_o = BMS/EMS$ on $(n-1)$ and $(n-1)(k-1)$ degrees of freedom. If we define

$$F_L = F_o / F_{1-\frac{1}{2}\alpha}[(n-1), (n-1)(k-1)]; \quad (8)$$

$$F_U = F_o \cdot F_{1-\frac{1}{2}\alpha}[(n-1)(k-1), (n-1)], \quad (9)$$

then

$$\frac{F_L - 1}{F_L + (k-1)} < \rho < \frac{F_U - 1}{F_U + (k-1)}$$

is a $(1-\alpha)\cdot 100\%$ confidence interval for ρ.

Decision 2: Can Effects Due to Judges Be Ignored in the Reliability Index?

In the previous section we stressed the importance of distinguishing Case 1 from Cases 2 and 3. In this section we discuss the choice between Cases 2 and 3. Most simply the choice is whether the raters are considered random effects (Case 2) or fixed effects (Case 3). Thus, under Case 2 we wish to generalize to other raters within some population, whereas under Case 3 we are interested only in a single rater or a fixed set of k raters. Of course, once the appropriate case is identified,

the choice of indices is between $ICC(2, 1)$ and $ICC(3, 1)$, as discussed before.

Most often, investigators would like to say that their rating scale can be effectively used by a variety of judges (Case 2), but there are some instances in which Case 3 is appropriate. Suppose that the reliability study (the G study) precedes a substantive study (the decision study in Cronbach et al.'s terms) in which each of the k judges is responsible for rating his or her own separate random sample of targets. If all the data in the final study are to be combined for analysis, the judges' effects will contribute to the variability of the ratings, and the random model with its associated $ICC(2, 1)$ is appropriate. If, on the other hand, each judge's ratings are analyzed separately, and the separate results pooled, then interjudge variability will not have any effect on the final results, and the model of fixed judge effects with its associate $ICC(3, 1)$ is appropriate.

Suppose that the substantive study involves a correlation between some reliable variable available for each target and the variable derived from the judges' ratings. One may either determine the correlation for the entire study sample or determine it separately for each judge's subsample and then pool the correlations using Fisher's z transformation. The variability of the judges' effects must be taken into account in the former case, but can be ignored in the latter.

Another example is a comparative study in which each judge rates a sample of targets from each of several groups. One may either compare the groups by combining the data from the k judges (in which case the component of variance due to judges contributes to variability, and the random effects model holds) or compare the groups separately for each judge and then pool the differences (in which case differences between the judges' mean levels of rating do not contribute to variability, and the model of fixed judge effects holds).

When the judge variance is ignored, the correlation index can be interpreted in terms of rater consistency rather than rater agreement. Researchers of the rating process may choose between $ICC(3, 1)$ and $ICC(2, 1)$ on the basis of which of these concepts they wish to measure. If, for example, two judges are used to rate the same n targets, the consistency of the two ratings is measured by $ICC(3, 1)$, treating the judges as fixed effects. To measure the agreement of these judges, $ICC(2, 1)$ is used, and the judges are considered random effects; in this instance the question being asked is whether the judges are interchangeable.

Bartko (1976) advised that consistency is never an appropriate reliability concept for raters; he preferred to limit the meaning of rater reliability to agreement. Algina (1978) objected to Bartko's restriction, pointing out that generalizability theory encompasses the case of raters as fixed effects. Without directly addressing Algina's criticisms, Bartko (1978) reiterated his earlier position. The following example illustrates that Bartko's blanket restriction is not only unwarranted but can also be misleading.

Consider a correlation study in which one judge does all the ratings or one set of judges does all the ratings and their mean is taken. In these cases, judges are appropriately considered fixed effects. If the investigator is interested in how much the correlations might be attenuated by lack of reliability in the ratings, the proper reliability index is $ICC(3, 1)$, since the correlations are not affected by judge mean differences in this case. In most cases the use of $ICC(2, 1)$ will result in a lower value than when $ICC(3, 1)$ is used. This relationship is illustrated in Tables 2, 3, and 4.

Although we have discussed the justification of using $ICC(3, 1)$ with reference to the final analysis of a substantive study, in many cases the final analytic strategy may rest on the reliability study itself. Consider, for example, the case discussed above in which each judge rates a different subsample of targets. In this instance the investigator can either calculate correlations across the total sample or calculate them within subsamples and pool them. If the reliability study indicates a large discrepancy between $ICC(2, 1)$ and $ICC(3, 1)$, the investigator may be forced to consider the latter analytic strategy, even though it involves a loss of degrees of freedom and a loss of computational simplicity.

Decision 3: What Is the Unit of Reliability?

The *ICC* indices discussed so far give the expected reliability of a single judge's ratings. In the substantive study (D study), often it is not the individual ratings that are used, but rather the mean of m ratings, where m need not be equal to k, the number of judges in the reliability study (G study). In such a case the reliability of the mean rating is of interest; this reliability will always be greater in magnitude than the reliability of the individual ratings, provided the latter is positive (cf. Lord & Novick, 1968).

Only occasionally is the choice of a mean rating as the unit of analysis based on substantive grounds. An example of a substantive choice is the investigation of the decisions (ratings) of a team of physicians, as they are found in a hospital setting. More typically, an investigator decides to use a mean as a unit of analysis because the individual rating is too unreliable. In this case, the number of observations (say, m) used to form the mean should be determined by a reliability study in pilot research, for example, as follows. Given the lower bound, ρ_L, on ρ from Inequality 6 or Inequality 7, whichever is appropriate, and given a value, say ρ^*, for the minimum acceptable value for the reliability coefficient (e.g., $\rho^* = .75$ or $.80$), it is possible to determine m as the smallest integer greater than or equal to

$$m = \frac{\rho^*(1 - \rho_L)}{\rho_L(1 - \rho^*)}.$$

Once m is determined, either by a reliability study or by a choice made on substantive grounds, the reliability of the ratings averaged over m judges can be estimated using the Spearman–Brown formula and the appropriate *ICC* index described earlier. When data from m judges are actually collected (e.g., in the D study following the G study used to determine m), they can be used to estimate the reliabilities of the mean ratings in one step, using the formulas below. In these applications, $k = m$. The formulas correspond to $ICC(1, 1)$, $ICC(2, 1)$, and $ICC(3, 1)$, and the significance test for each is the same as for their corresponding single-rater reliability index.

The index corresponding to $ICC(1, 1)$ is $ICC(1, k) = (BMS - WMS)/BMS$. Letting F_L and F_U be defined as in Equations 4 and 5,

$$1 - \frac{1}{F_L} < \rho < 1 - \frac{1}{F_U}$$

is a $(1 - \alpha) \cdot 100\%$ confidence interval for the population value of this intraclass correlation.

The index corresponding to $ICC(2, 1)$ is

$$ICC(2, k) = \frac{BMS - EMS}{BMS + (JMS - EMS)/n}.$$

The confidence interval for this index is most easily obtained by using the confidence bounds obtained for $ICC(2, 1)$ in the Spearman–Brown formula. For example, the lower bound for $ICC(2, k)$ is

$$\rho_L = \frac{k\rho_L^{**}}{1 + (k - 1)\rho_L^{**}},$$

where ρ_L^{**} is the lower bound obtained for $ICC(2, 1)$.

For $ICC(3, 1)$, the index of consistency for the mixed model case, the generalization from a single rating to a mean rating reliability is not quite as straightforward. Although the covariance between two ratings is $\sigma_T^2 - \sigma_I^2/(k - 1)$, the covariance between two means based on k judges is σ_T^2. As we pointed out before, under Case 3 no estimator exists for this term.

If, however, the Judge × Target interaction can be assumed to be absent, then the appropriate index is

$$ICC(3, k) = (BMS - EMS)/BMS.$$

Letting F_L and F_U be defined as in Equations 8 and 9,

$$1 - \frac{1}{F_L} < \rho < 1 - \frac{1}{F_U}$$

is a $(1 - \alpha) \cdot 100\%$ confidence interval for the population value of this intraclass correlation. $ICC(3, k)$ is equivalent to Cronbach's (1951) alpha; when the ratings of observers are dichotomous, it is equivalent to the Kuder–Richardson (1937) Formula 20.

Sometimes the choice of a unit of analysis causes a conflict between reliability considerations and substantive interpretations. A mean of k ratings might be needed for reliability, but the generalization of interest might be individuals.

For example, Bayes (1972) desired to relate ratings of interpersonal warmth to nonverbal communication variables. She reported the reliability of the warmth ratings based on the judgments of 30 observers on 15 targets. Because the rating variable that she related to the other variables was the mean rating over all 30 observers, she correctly reported the reliability of the mean ratings. With this index, she found that her mean ratings were reliable to .90. When she interpreted her findings, however, she generalized to single observers, not to other groups of 30 observers. This generalization may be problematic, since the reliability of the individual ratings was less than .30—a value the investigator did not report. In such a situation in which the unit of analysis is not the same as the unit generalized to, it is a good idea to report the reliabilities of both units.

Conclusion

It is important to assess the reliability of judgments made by observers in order to know the extent that measurements are measuring anything. Unreliable measurements cannot be expected to relate to any other variables, and their use in analyses frequently violates statistical assumptions. Intraclass correlation coefficients provide measures of reliability, but many forms exist and each is appropriate only in limited circumstances.

This article has discussed six forms of the intraclass correlation and guidelines for choosing among them. Important issues in the choice of an appropriate index include whether the ANOVA design should be one way or two way, whether raters are considered fixed or random effects, and whether the unit of analysis is a single rater or the mean of several raters. The discussion has been limited to a relatively pure data analysis case, k observers rating n targets with no missing data (i.e.. each of the n targets is rated by exactly k observers). Although we have implicitly limited the discussion to continuous rating scales, Feldt (1965) has reported that for $ICC(3, k)$ at least, the use of dichotomous dummy variables gives acceptable results. Readers interested in agreement indices for discrete data, however, should consult the Fleiss (1975) review of a dozen coefficients or the detailed review of coefficient kappa by Hubert (1977).

VOLUME 86 / NUMBER 3 MAY 1979

Psychological Bulletin

(Continued on inside back cover)

LISHED BIMONTHLY BY THE AMERICAN PSYCHOLOGICAL ASSOCIATION
ISSN 0033-2909

The *Psychological Bulletin* publishes evaluative reviews and interpretations of substantive and methodological issues in the psychological research literature. The Journal reports original research only when it illustrates some methodological problem or issue. Discussions of methodological issues should be aimed at the solution of some particular research problem on psychology, but should be of sufficient breadth to interest a wide readership among psychologists; articles of a more specialized nature can be directed to the various statistical, psychometric, and methodological journals. The *Bulletin* does not publish original theoretical articles; these should be submitted to the *Psychological Review*.

Abstracts: All articles must be preceded by an abstract of 100–175 words. Detailed instructions for preparation of abstracts appear in the *Publication Manual of the American Psychological Association* (2nd ed.), or they may be obtained from the Editor or from APA Central Office.

Blind review: Because reviewers have agreed to participate in a blind reviewing system, authors submitting manuscripts are requested to include with each copy of the manuscript a cover sheet, which shows the title of the manuscript, the name of the author or authors, the author's institutional affiliation, and the date the manuscript is submitted. The first page of the manuscript should omit the author's name and affiliation but should include the title of the manuscript and the date it is submitted. Footnotes containing information pertaining to the author's identity or affiliation should be on separate pages. Every effort should be made to see that the manuscript itself contains no clues to the author's identity.

Manuscripts: Submit manuscripts in triplicate to the Editor, R. J. Herrnstein, *Psychological Bulletin,* Harvard University, 33 Kirkland Street, Cambridge, Massachusetts 02138, according to instructions provided below.

Instructions to Authors: Authors should follow the directions given in the *Publication Manual of the American Psychological Association* (2nd ed.). Instructions on tables, figures, references, metrics, and typing (all copy must be double-spaced) appear in the Manual. Authors are requested to refer to the "Guidelines for Nonsexist Language in APA Journals" (Publication Manual Change Sheet 2, *American Psychologist,* June 1977, pp. 487–494) before submitting manuscripts to this journal. All manuscripts should be submitted in duplicate and both copies should be clear, readable, and on paper of good quality. Dittoed copies are not acceptable and will not be considered. Authors are cautioned to carefully check the typing of the final copy and to retain a copy of the manuscript to guard against loss in the mail.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1979: $40 domestic, $42 foreign, $7 single issue. APA member rate: $15. Write to Subscription Section, APA.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Dept., APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Published bimonthly (beginning in January) in one volume per year by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Arlington, Va., and at additional mailing offices.

Equity Theory and the Cognitive Ability of Children

J. G. Hook and Thomas D. Cook
Northwestern University

A number of studies indicate that preadolescents allocate more rewards to those who have done more work. Adams's equity theory is most often used to explain this finding. One assumption of equity theory is that persons compute ratios and compare them for proportionality. However, research on logico-mathematical development indicates that children do not solve problems of proportionality until they are 11–15 years old. This suggests that equity theory may not be an adequate explanation of how children allocate rewards in experiments on equity. Children's allocation behaviors do change with age, from the possibly self-interested or equal allocations of children under 6 years, to the descriptive ordinal equity allocations of 6- to 12-year-olds, to the possibly proportional allocations of persons 13 years and older. This sequence is consistent with the normal sequence of logico-mathematical development, suggesting that observed allocation behaviors may be a function of cognitive ability as well as manipulated situational variables.

Adams's (1965) equity theory is a cognitive social comparison theory. It is concerned with the cognitive activity of the individual who is confronted with a problem of distributive justice. We call this individual the *allocator*. Adams assumed that the allocator constantly compares persons, including the allocator, on two dimensions: outcomes and inputs. Inputs are contributions (e.g., labor) or attributes (e.g., being well educated) that justify claims on outcomes. Outcomes are rewards or desirable things, which can be either tangible (e.g., pay) or intangible (e.g., love). Adams assumed that the allocator first forms ratios of outcomes to inputs for each comparison person. Next, the allocator compares the ratios. If they are equivalent, or proportional, equity obtains. If they are not proportional for any two comparison persons, inequity is assumed to result. Thus, inequity obtains when

$$\frac{\textit{Outcomes for Person X}}{\textit{Inputs by Person X}} \neq \frac{\textit{Outcomes for Person Y}}{\textit{Inputs by Person Y}}.$$

If inequity obtains, Adams assumed that the allocator will recognize it and feel a sort of discomfort. This discomfort is then assumed to motivate the allocator to restore equity, either directly (e.g., by redistributing rewards) or by cognitive distortion.

Adams's equity theory incorporates the value principle that there should be a rela-

tionship of proportionality between inputs and outcomes, between work and reward; that is, rewards should be allocated according to merit. Each allocator, however, has substantial latitude in determining the content of equity, because the allocator alone determines which particular factors to include as inputs and outcomes and how each should be weighted. Adams's theory is not an ethical theory because he did not say equitable allocations were good. Rather, he predicted that people would behave as if they believed equitable allocations were good. According to Adams, people behave that way because they are responsive to a social norm that prescribes equitable allocations and proscribes other allocations. The equity norm is presumably the cause of the allocator's discomfort when the allocator recognizes inequity.

Few equity theorists believe that the equity norm is always applicable. Rather, the norm is presumed to guide behavior in certain situations and not in others. When the equity norm is not situationally appropriate, other norms may be relevant. The equality norm (Sampson, 1969), for example, commands that persons receive the same outcomes, no matter what their inputs. Self-interest, which is perhaps a genetically influenced norm (Campbell, 1972), commands that persons maximize their own share. A norm for altruism (Bryan, 1972) commands the opposite. Other hypothesized norms, less relevant to this article, include reciprocity (Schopler, 1970; Staub, 1972) and "to each according to his need" (Berkowitz, 1972; Leventhal, Weiss, & Buttrick, 1973).

Most allocation research has been designed to identify the personal and situational variables that influence an allocator's choice of norms. For example, research indicates that under some conditions females make equal allocations of reward regardless of relative work (Uesugi & Vinacke, 1963), whereas males make equitable allocations (Vinacke & Stanley, Note 1). Under different conditions the reverse can be true (Kidder, Bellettirie, & Cohn, 1977). Other empirical work suggests that allocators make equal allocations when group harmony is a salient concern (Smith & Cook, 1973), but make equitable allocations when productivity is a salient concern (Leventhal, Michaels, & Sanford, 1972).

In the first study in which equity theory was used to predict children's allocation behaviors, Leventhal and Anderson (1970) led individual children to believe that they were members of dyads doing work for the experimenters. One independent variable was the sex of the child. The second involved a manipulation of the amount of work a child did relative to the amount he was led to believe that his (unseen) partner had performed. This relative-work information was the only information each child was given about his partner. Each child was assigned to one of three work conditions: superior work (three times as much work as the partner in a 15:5 ratio), equal work (same amount of work in a 15:15 or 5:5 ratio), and inferior work (one third as much work in a 5:15 ratio). The dependent measure was the number of rewards, out of a total of 20, that each child kept for himself when he was asked to distribute the rewards anonymously between himself and the other child in any way he desired. Equity theory was used to predict that the children would keep the same proportion of rewards as the proportion of work they had done. For example, the inferior-work child's *equity cognition* appeared first as the dilemma

$$\frac{\textit{My work} = 5}{\textit{My reward} = ?} = \frac{\textit{Other's work} = 15}{\textit{Other's reward} = ?},$$

to be resolved as $5/5 = 15/15$. Thus, equity theory, which assumes that the allocator forms ratios in his head and compares them for *proportional equity*, predicts that superior-, equal-, and inferior-work subjects should keep 15, 10, and 5 rewards, respectively.

Table 1 shows the results of the Leventhal and Anderson study. Recall that the scores could range from 0 to 20, with 10 indicating that the child divided rewards equally between himself and the other child. The means for females do not differ significantly from each other or from 10. This suggests that under the conditions of this experiment the

female allocators were influenced by an equality norm. Males in the superior-work (15 units) condition kept significantly more for themselves than did males in the two equal-work conditions. This result seems to support an equity norm interpretation. However, it does not support an equity interpretation in the strictest sense of Adams's theory. Rather, it is an *ordinal equity,* in which rank order is preserved from the work dimension to the reward dimension. The mean value of 12.7 is halfway between the proportional equity predicted by equity theory (i.e., 15) and the *equality norm* (10). We henceforth assume that such behavior reflects ordinal equity.

It is crucial to understand that even if the superior workers kept larger rewards and the inferior workers smaller rewards (although the latter did not occur in this study), such results would not necessarily be consistent with equity theory. This is because the theory requires that workers keep the same proportion of rewards as their proportion of work. Thus, results like those found with the superior-work males of Leventhal and Anderson cannot readily be interpreted in terms of equity theory alone. One would have to assume that proportional equity is operating together with other forces influencing allocation, or that some alternative (e.g., ordinal equity) is involved.

Table 1
Mean Number of Rewards Kept by Subjects in Leventhal and Anderson (1970)

Subject's work unit	Partner's work unit: 5	Partner's work unit: 15

Actual *M* no. rewards	10.6	11.1
15		
Theoretical no. rewards	15	10
Actual *M* no. rewards	12.7	10.3

Before we move to the literature review it is important that we briefly review two key aspects of equity theory. In the Leventhal and Anderson (1970) study, equity was inferred from the reward allocations of children from different input groups, and there was no explicit comparison with the precise scores predicted by the proportional equity theory. In other words, the hypotheses and independent variables were derived from a theory that assumes interval scales for the input and outcome variables, but inferences about equity were made merely on the basis of ordinal group differences on the dependent variable. It is as though equity researchers are content to infer equity if the mean differences are in the expected direction, irrespective of whether they differ from the theoretically specified numerical differences. The justifications for such slippage are presumably (a) that experiments cannot control all inputs and outcomes and that some of the nonmanipulated variables that subjects make relevant to a particular equity ratio may codetermine their allocative behavior; (b) that equity may be aroused simultaneously with other norms that codetermine allocation; and (c) that equity theory should be understood as a general metaphor for studying allocative behavior rather than as a formal theory pretending to completeness and specificity. Unfortunately, equity theorists are rarely explicit about the reasons for inferring equity from ordinal patterns of data that are in line with, but different from, the more exact interval-scale predictions that the theory appears to make.

Second, equity theory makes somewhat extreme assumptions about the cognitive activity of the allocator. Recall that the theory states that an allocator feels discomfort when equity ratios are not proportional. Almost all tests of equity leave this discomfort unmeasured and thus assumed. Logically prior to this feeling is the assumption that the allocator sets up and compares ratios. Still prior is the assumption that the allocator is competent to set up and compare ratios. Then, of course, there is the large assumption that the allocator is able to conceptualize heterogeneous outcomes (e.g., satisfaction or dol-

lars) and heterogeneous inputs (the quantity and quality of work or qualifications) and is able to weld them into a single, unidimensional scale of outcomes or inputs. It may or may not be true that adults go through such a cognitive process, of which they may well be capable under some conditions This article is concerned with whether children are capable of such cognitive activities and whether they actually perform them.

Allocation Literature: Children and Adults

Framework for the Literature Review

Table 2 is a summary of the allocation literature. Two types of studies are included. The Leventhal and Anderson (1970) study is an example of one type, in which subjects are allowed to compare the work inputs of persons and then are asked to distribute rewards (outcomes) among the persons who have performed work. The Libby and Garrett (1974) study is an example of the second type, in which the allocator is asked to distribute rewards between persons who did equal work throughout but were unequally rewarded in a previous allocation.

Two types of allocation studies are excluded because they do not involve work comparisons and reward allocations among the same persons. First, in "helping" studies, allocators are asked to donate some of their rewards to a third party who did not work (Long & Lerner, 1974; Miller & Smith, 1977; Staub, Note 2) or are asked to share an unearned gift with a friend or stranger (Ugurel-Semin, 1952; Wright, 1942a, 1942b). Second, in some equity studies, all the work and outcome values are told to subjects, making the computation of an equity formula a fait accompli. The dependent measures are

such factors as subjects' ratings of the allocator's attractiveness or fairness (Brickman & Bryan, 1975, 1976) or the quality of the subject's continued performance under some preestablished allocation rule (Lawler, 1968).

The explicit condition from Nelson and Dweck (1977) is excluded from Table 2. This is because children were instructed to give out rewards "so that you get the right amount for doing this much work" (p. 194), and then had a chance to physically copy in their reward allocation what the work differences had been. In the research reported in Table 2, children were instructed to allocate rewards in a fair manner or in whatever manner they wanted, and copying was not explicitly requested.

The studies in Table 2 are arranged according to the ages of the subjects. Studies of multiple age groups are reported multiple times in appropriate age positions. The column labeled Class indicates whether the subjects who were asked to allocate rewards were participants in the work and potential reward recipients (P studies) or were disinterested third party observers of others' work (3rd studies).

The column labeled Result classifies each study with respect to the allocation principle the mean scores seem to indicate the subjects followed. The four classes of results are self-interest, equality, ordinal equity, and proportional equity. Self-interest could only occur in P studies, which means the subjects kept more for themselves than they allocated to others, no matter how much work each had done. Equality, ordinal equity, and proportional equity are defined with respect to the Equity Quotient column. The equity quotient is a numerical index of the extent to which the study results are consistent with Adams's proportional equity. The quotient is the ratio of the percentage point differences between experimental conditions predicted by proportional equity theory to the differences between experimental conditions in the observed allocation behaviors. For example, in Leventhal and Anderson (1970) the inferior-work males should have kept 25% of the reward because they did 25% of the work. The superior-work males should have kept 75% of the reward because they did 75% of the work. Thus, the gap between the two groups predicted by proportional equity theory is 50 percentage points (75 − 25 = 50). The actual difference between the two experimental conditions, in terms of their actual allocation behaviors, was 8 percentage points. This is because the interior-work group kept an average of 55.5% of the reward, whereas the superior-work group kept an average of 63.5%. The ratio of the observed gap (8) to the predicted gap (50) is therefore .16 (8/50), which is the quotient reported in Table 2 for the males from Leventhal and Anderson. (Actually, all values in the table have been multiplied by 100 to avoid decimal points.)

The ratio in Leventhal and Anderson can be expressed visually as

Observed: 55.5.....63.5 = 8

Predicted: 25.0.............75.0 = 50.

A quotient of zero means that subjects did not differentiate their reward allocations:

Observed: 50–50 = 0

Predicted: 25.0.............75.0 = 50.

A quotient of 100 means that subjects made reward allocations precisely as predicted by proportional equity theory:

Observed: 25.............75 = 50

Predicted: 25.............75 = 50.

A quotient of 50 is the prototypical ordinal equity relationship, with observed scores falling between the equality and the proportional equity predictions:

Observed: 37.5.....62.5 = 25

Predicted: 25.............75 = 50.

In Table 2, then, scores between 0 and 25 are labeled *equality* or *self-interest*. Scores between 26 and 75 are called *ordinal equity*, and scores greater than 75 are labeled *proportional equity*.[1]

[1] If a study included only one work condition (Larsen & Kellogg, 1974) or more than two persons in the reward allocations (Streater & Chertkoff,

Relationship Between Age and Equity

The studies in Table 2 and other allocation studies suggest that a number of independent variables influence children's reward allocations. Children's allocation behaviors may be influenced by whether the allocator is a participant or a third party, whether the participants are in a team or nonteam relationship (Lerner, 1974), and whether they are cooperating or competing (Crockenberg, Bryant, & Wilce, 1976), expect future interactions with each other (Dreman, 1976), are male or female (Leventhal & Anderson, 1970), believe the experimenter will or will not evaluate their allocations (Leventhal, Popp, & Sawyer, 1973), and have insufficient, sufficient, or oversufficient total reward to allocate (Coon, Lane, & Lichtman, 1974).

However, the independent variable of special interest for this article is age, especially as it mediates logical development. The most striking age-linked feature of Table 2 is that the proportional equity responses predicted by equity theory are entirely absent in studies of subjects under 13 years of age. On the other hand, the results provide strong support for an alternative, ordinal equity interpretation with children. Three sets of studies are especially interesting in this regard because the same investigators employed the same designs with children 12 years of age or under and with children or adults of 13 years and over. The equity quotient scores for 5.9-year-old children in Leventhal and Anderson (1970) were 16 for males and 1 for females, whereas adult quotients in Leventhal and Lane (1970) were 79 for both males and females. Libby and Garrett's (1974) 6- and 8-year-olds gave quotients of 60 and 53, respectively, whereas Garrett and Libby's (1973) 14-year-olds gave a quotient of 96. Hook's (1978) 5-, 9-, and 13-year-olds gave quotients of 22, 56, and 94, respectively. The average equity quotient in studies of children under 13 years was 36.9, whereas the average quotient for 13-year-olds and above was 79.9. Proportional equity, therefore, appears to be restricted to the teen years and beyond.

How can one explain the ordinal equity of childhood? Five possibilities are discussed below.

Confounded inputs interpretation. One interpretation is that children use other inputs in addition to work in their proportional equity equations. For example, suppose most children felt that need should be weighed as heavily as work. Since most studies provided no information about the other's need, the average subject might assume that he and the other were equal on need. If so, the superior-work subject would have total inputs somewhat greater than the other, but not so much greater than if he had used only work in forming inputs. Thus, in allocating rewards proportional to inputs, the superior workers would make what, to the researcher who was not aware of the hidden need input, looked like an ordinal equity allocation. Yet the allocation might be based on proportional equity. (As with inputs, a subject could also add hidden outcomes or rewards to those manipulated by an experimenter.) The uncontrolled-inputs-and-outcomes problem is a major weakness of equity theory, making falsification extremely difficult. No matter what reward allocation a subject made, it could be argued that he was behaving equitably on the basis of some uncontrolled intruding input or outcome.

Nonisomorphism of physical and psychological scales. A second interpretation follows from the possibility that preadolescents transform the physical work scales into psychological scales of a different form. If so, one can imagine circumstances in which descriptive ordinal allocation data can be interpreted as consequences of proportional thinking of the type suggested by Adams (1965). But it is proportional thinking based on psychological scales that are not linear functions of the corresponding physical scales.

Intra-allocator norm combination. A third interpretation of the ordinal equity data of

---

1976), no quotient could be calculated. Also, in two studies (Anderson, 1976; Anderson & Butzin, 1978) the independent manipulations were on an ordinal scale (e.g., one child gave little effort and the other average effort) rather than on a ratio scale (e.g., 15/5), which did not allow quotient calculation. These few studies are classified on logical grounds.

younger children is that they are simultaneously aware of the allocations appropriate to equality and proportional equity norms but resolve any dilemmas associated with the different norms by taking the average. Such a compromise yields an ordinal equity allocation. This interpretation holds that older children have clear preferences for proportional equity over equality norms, which is why their data reflect proportional rather than ordinal equity. No data exist of which we are aware that probe whether children under about 13 years of age consider both equality and proportional equity norms before deciding on a compromise between the two.

Interallocator norm combination. A fourth interpretation is that some younger children make equality allocations, whereas others make proportional equity allocations. The average scores in this case would look like ordinal equity allocations. However, such an interpretation requires a bimodal distribution of allocations. Hook's (1978) data are not bimodally distributed, and no published study mentions a bimodal distribution or reports group differences in variances for the allocation measure. Consequently, the interpretation based on the interallocator norm combination does not seem likely.

Inability interpretation. A fifth interpretation, the primary concern of this article, is that children under the age of 13 are typically incapable of solving problems of ratio proportionality. If this were true, it would rule out the first three interpretations, since all three assume that half or more of the children are engaged in the cognitive, ratio-proportionality activity posited by equity theory. The inability interpretation implies that children do not weight several norms to decide which to apply in a given situation because it postulates that children are incapable of recognizing proportional equity. However, the inability explanation does not rule out the possibility that children under 13 years of age may be capable of acquiring and expressing work–reward relationships in an ordinal equity sense, assuming that ordinal equity is an earlier acquisition than is proportional equity.

To decide whether children under the age of 13 can solve problems of proportional or ordinal equity, we turn to the literature on logico-mathematical development: the interview work of Piaget's school and the more statistical, normative work of other investigators.

Development of Proportional Thought

Table 3 is a list of Piaget's studies of the development of logico-mathematical proportion. The column labeled Task refers to the particular problem used by Piaget to explore proportional thought. According to his theory, proportional thought is a cognitive structure that is central to, or embedded in, all kinds of mathematical, physical, and social problems. Piaget has not studied proportional thought directly. Rather, he has studied it in the context of his research on such diverse yet proportion-dependent areas as geometry, chance, time, and functions. Piaget and his colleagues usually conduct clinical interviews with children of different ages and classify their responses into age-related stages. Each stage is supposed to represent a qualitatively different approach, and the stages are thought to unfold in an invariant sequence, which culminates in mature proportionality, the stage at which all logical components have been integrated into a coherent structure. The column labeled Attainment Age in Years refers to the approximate age that Piaget's subjects attained the stage of proportional thought. Piaget was not very explicit about how the attainment age was defined, and it is obvious that the age depended on certain task factors, for example, perceptual and memory requirements. Therefore, the attainment ages should be considered estimates.

To illustrate Piaget's approach, we consider two of his studies. In studies of the development of the concept of speed, Piaget (1970) asked children to trace and time the movements of two objects, A and B, that ran in succession. The children were then asked which moved faster. The youngest children did not transfer the ordinal rank of the objects from distance traveled to speed. In other words, if A moved farther than B in

Table 3

	Covarying different-size circles with different line positions	7–13	12–13
	Relative movements of wheels of different diameters	6–13	11–13
	Relative movements of objects pulled by different-diameter pulleys	6–14	12–14
	Equilibrium on a balance arm	6–14	12–13
Piaget (1970)	Drawing lines to symbolize relative speeds of objects	5–14	12–13
Piaget (1974)	Stretching elastic bands and guessing relative lengths of segments	5–14	13–14
	Maintaining angles formed by strings held fast with different angles	5–14	13–14
	Guessing the number of small unit beakers necessary to fill larger beakers	5–14	13–14
Piaget & Inhelder (1975)	Probabilities of lottery drawing outcomes from beakers containing various ratios of elements	5–14	11–12

the same amount of time, these children did not necessarily say that A moved faster. The 7- to 9-year-olds did make the transformation, but only if either distance traveled or time was held constant. If time and distance were varied simultaneously, the 7- to 9-year-olds were unable to set up the necessary ratios of distance to time for comparison:

$$\frac{\textit{Distance for A}}{\textit{Time for A}} = \frac{\textit{Distance for B}}{\textit{Time for B}}.$$

This problem is of course highly analogous to the equity theory problem, if one substitutes outcomes for distance and inputs for time.

The 10- and 11-year-olds could often solve the two-variable problem for simple 2:1 ratios. However, their solutions may have been intuitive instead of formal. They did not seem to be able to explain why they guessed as they did. Only 12- to 14-year-olds could solve the problems for more complex ratios and state the principle that distance divided by time equals speed.

Piaget (1974) obtained analogous results by asking children to estimate the lengths of elastic band segments. The bands were divided into Segments A and B, distinguished by color. Segment A was longer than Segment B by various ratios. For example, in a 2:1 ratio problem, the elastic band at rest was 3 cm long, with segments of 2 cm (A) and 1 cm (B). The band was then stretched to lengths that were multiples of its rest length, for example, doubled to 6 cm. Before the children could examine the segments of the expanded band, they were asked how long each segment should be. The youngest children (4–5 years) failed to preserve ordinality through the transformation, not realizing that A should be longer than B. Somewhat older children (6–9 years) noted that A should be longer, but did not preserve the ratio relationships between A and B. Rather,

Table 4

they preserved the additive relationship. If Segment A was 1 cm longer than Segment B before the stretching $(2 - 1 = 1)$, it should have been 1 cm longer afterwards $(4 - 3 = 1)$. The oldest children discovered the ratio solution first on an intuitive level and with small (2:1) ratios and then, at about 13 years of age, on a formal basis with complex ratios.

Piaget's other studies yielded results quite analogous to the two examples. The developmental stages seem to unfold in the same sequence no matter what task is used. The age of attainment varies somewhat depending on the task, but in all cases it is between 10 and 15 years of age, averaging about 13 years of age.

Piaget's methodology has been criticized as being too clinical. Table 4 is a summary of research carried out by non-Piagetian psychologists. Many of these studies employed the large samples, statistical analyses, and standardized problem presentation and response modes that are missing in the Piagetian research. The attainment ages mentioned in the table refer to the age at which half or more of the subjects had demonstrated proportional thought, if it was possible to glean this information from the published reports. In general, the studies in

Table 4 are consistent with Piaget's results. They document the same acquisition stages and the fact that mature proportional thought is not developed until adolescence. However, these attainment ages are a year or two later than those reported by Piaget.

Implications of the Literature Review

Our review of the literature on logic–mathematics development indicates that the average child under 13 years of age does not solve problems of ratio proportionality. There is no evidence with physical and mathematical problems that preteens cognitively construct and compare ratios, just as there is no evidence for similar cognitive activity in the allocation literature. Our review offers no support for the equity theory assumptions that preteens form cognitive ratios and feel discomfort in the absence of proportionality. The major methodological and theoretical implications of the review are now spelled out.

Methodological Implications

Our negative conclusions about the relevance of Adams's (1965) proportional equity theory for children under 13 years have to be tentative. They must be interpreted in the light of several issues. The research summarized in Tables 3 and 4 does not necessarily demonstrate that children under 13 years are incapable of proportional solutions to logico-mathematical problems. It may only show that they do not perform behavior commensurate with such thinking. The studies cited in these tables were open ended, and children were asked to respond in whatever manner they wished. Generally, they were not told that there was a right answer that they must find; no incentives were provided to induce children to perform in ways indicative of proportional thinking; and the studies did not follow the training or enrichment paradigm whereby a child is told a correct response and is reinforced for replicating it. Brainerd and Allen (1971) claimed that corrective feedback over a series of trials on conservation of density induced this capacity in 10- and 11-year-olds who at first failed to conserve and did not seem to have the capacity. The trained children not only conserved density at a higher rate than a control group but also apparently generalized their learning to problems in conservation of volume. Varying training, instructional sets, and incentives to reveal capacities that are not spontaneously manifested may provide evidence of proportional capacity in younger children. We do not know, since the appropriate studies have not yet been performed.[2] Until they are, it will not be clear whether the age norms for both allocative behaviors and logico-mathematical skills are due to the biological constraints of maturation or to environmental factors that lead children not to perform behavior of which they are indeed capable under certain conditions. (See Brainerd, 1978, for a discussion of this problem.)

Even if one assumes that preteens are incapable of proportional responses to logico-mathematical problems, does this mean they are incapable of such responses to allocation dilemmas? Our response must be, "We are not yet sure," largely because of the possibility of confounded inputs and nonisomorphic psychological and physical scales. But on the other hand, our review does suggest that behaviors in the allocative and logico-mathematical domains are highly congruent. Also, a number of studies (Damon, 1975; Hook, 1978; Tompkins & Olejnik, 1978) document correlations between responses to the two types of problem. However, such relationships do not show which type, if either, is prior. Future research is needed to test the idea, implicit in our review, that the logico-mathematical proportionality concept develops either prior to, or simultaneous with, the allocational proportionality concept.

Some experimental features may permit children to make allocations that are entirely consistent with proportional equity but are not the result of engaging in proportional cognitions. The first such feature in-

[2] The experiment by Brainerd and Allen (1971) did not involve feedback on actual numerical distributions, and their subjects could have given proportionality responses without ratio cognitions.

volves the recognition of equity as a dependent behavior rather than the creation of equity. Brickman and Bryan (1976), for example, showed children videotapes in which characters transferred rewards from one person to another and either created or eliminated proportional equity. The children then rated the transfer agent. Agents who created equity were viewed more favorably than those who eliminated it. Thus, the children did not create an equitable allocation, but recognized one.

A second feature involves the use of correspondent allocation problems. Using the Leventhal and Anderson (1970) paradigm, suppose that two persons contribute 15 and 5 inputs, respectively, and then must distribute 20 outcome rewards. A proportional equity allocation could be created by setting outcomes in exact correspondence to inputs for each person: 15 for 15 and 5 for 5. This allocation requires no knowledge of ratios. Nelson and Dweck (1977), for example, asked 4-year-olds who had done either nine or three units of work to divide 12 rewards. In the conditions in which they specifically instructed children to make allocations consistent with work, all of the children made proportional allocations. Although Nelson and Dweck argued that this demonstrated the capacity of even 4-year-olds to allocate in an equitable manner, Anderson and Butzin (1978) noted that such proportional allocations could have been due to correspondence procedures involving no social comparison or proportional cognition at all. Also, Nelson and Dweck observed proportional allocations only when they explicitly requested work–reward correspondence. In other conditions, Nelson and Dweck and other researchers using correspondence designs (Streater & Chertkoff, 1976; Tompkins & Olejnik, 1978) did not observe proportional allocations.

What if, however, two persons contributed three and one inputs, respectively, and were asked to allocate 20 rewards? Children could give 3 rewards to one worker and 1 to the other and then repeat the process until the 20 rewards were exhausted. This problem demands *iteration* but not ratio cognitions. It would be more plausible to assume ratio cognitions if the two workers contributed 6 and 2 units of work before allocating 20 rewards.

A third feature involves the *ordinal scaling* of the independent variable. Anderson and Butzin (1978) used adjectives to describe the work efforts of two persons. Persons X and Y were said to have tried "a little bit," "kind of hard," and "very hard." Children aged 6-, 8-, and 10-years-old were asked to allocate 20 candy rewards to X and Y under all nine possible combinations of relative work. Equity theory was employed to predict the allocations. For example, if X and Y both tried "very hard" they should have received equal numbers of rewards (10 each). If X tried "very hard" and Y tried "kind of hard," then X deserved more rewards. This equity prediction, however, is ordinal only, not proportional. If X receives more rewards than Y, no matter how many more, ordinal equity is supported. The input adjectives cannot be placed in a ratio.

The only way to differentiate ordinal and proportional equity predictions with such ordinally scaled independent variables is to assign numbers to the adjectives, such as *a little bit* = 1, *kind of hard* = 2, and so on. Assuming such an underlying interval scale, the nine data points in the Anderson and Butzin design that reflect allocation behavior would be spaced differently if the subjects employed an ordinal equity rule than if they employed a proportional equity rule. Granting such a scaling assumption, Anderson and Butzin's data with children are consistent with ordinal equity, whereas Anderson's (1976) earlier data with adults appear to be more consistent with proportional equity.

Finally, in interpreting the studies we have reviewed it is worth bearing in mind that we have stressed children's probable incapacity to generate the logical preconditions for calculating equity ratios. We have thereby assumed that it is more useful to consider equity theory in the proportional sense explicit in Adams's theoretical formulations than in the less strict sense implied by the belief of equity researchers that the theory is corroborated whenever the outcome data show ordinal relationships that are congru-

ent with the theory, even though the data do not attain the exact numerical values that the formal theory suggests. It is difficult to judge whether one should hold equity theory accountable in terms of the standards of the theory or in terms of the (more relaxed) standards of tests of the theory. We have opted for the former over the latter. But it is noteworthy that had we opted for the standard of past empirical tests, then the ordinal equity responses of children between 7 and 13 years of age would be interpreted as supporting equity theory rather than interpreted—as we have done—as not directly supportive.

Future tests of equity in young children would be improved if (a) they were explicit about the degree to which, as a theoretical construct, equity requires cognitive interval scaling and proportional thinking; (b) they incorporated experimental procedures that "unconfound" the capacity to think in ratio terms and the willingness to think this way or to perform behaviors indicative of such thinking; (c) they examined the ways in which the development of allocative skills and the development of logico-mathematical skills are temporally related to each other; and (d) they made sure that behaviors indicative of proportional thinking were not the results of correspondence procedures that do not necessarily require proportional thinking. Equity is a slippery construct that requires explicit formulation and the careful choice of experimental procedures that are carefully tailored to the preferred theoretical formulation. In these respects equity is like other justice constructs. (For a discussion of the construct validity of relative deprivation and the requirements of validation tests, see Cook, Crosby, & Hennigan, 1977.)

Theoretical Implications

Up to now we have made the point that equity theory in the proportional form proposed by Adams (1965) is probably inappropriate when applied to children under the age of 13. We have made this point (a) because on logico-mathematical tasks structurally analogous to equity tasks children do not behave in a manner consistent with the equity assumption that they form cognitive ratios and (b) because the allocative behavior of children in equity experiments is not entirely consistent with a proportional interpretation. However, we have also made the point that future research with better designs and procedures may produce results commensurate with proportional equity theory, though we are skeptical.

The research reported in Tables 3 and 4 suggests a three-step development of proportional thought, as evidenced by children's responses to logico-mathematical problems. Children under approximately 6 years of age do not preserve an ordinal relationship from one dimnesion (e.g., distance traveled) to another (e.g., speed). Middle school children from about 6 to 12 years old preserve such ordinal relationships by setting up corresponding series, but do not relate two dimensions in terms of fractions or ratios. Finally, adolescents and adults above 13 years of age can and do compare ratios for proportionality.

Table 5
Results of Allocation Research in Three Age Groups

Result	Age in years: 3–5	6–12	13+
Self-interest	5	0	0
Equality	11	4	0
Ordinal equity	5	29	4
Proportional equity	0	0	9

Table 5 reports the research results in Table 2 that are consistent with each of the four dominant allocation norms—self-interest, equality, ordinal equity, and proportional equity. The studies are divided into columns according to the ages of the subjects: 3- to 5-year-olds make what appear to be self-interest and equality allocations; 6- to 12-year-olds make what seem to be ordinal equity allocations; and 13-year-olds and older seem to prefer proportional equity allocations. Thus, allocation behaviors seem to follow a sequence of stages similar to those of thought in general and are roughly correspondent to Piaget's sequential stages of

Table 6
Three Steps in the Development of Allocation Behavior

Step	Comparison: Person A	Comparison: Person B	Probable onset age in years
Unidimensional	Outcome A ↔ Outcome B Input A ↔ Input B		3
Ordinal	Outcome A > Outcome B ↕ Input A > Input B		6
Proportional	$\frac{\text{Outcome A}}{\text{Input A}} \leftrightarrow \frac{\text{Outcome B}}{\text{Input B}}$		13

intellectual development: preoperational, concrete operational, and formal operational thought.

Unidimensional allocative comparisons of children under 6 years of age. Although self-interest and equality seem to be very different, they share one attribute not possessed by other allocation principles: Both require comparisons on one dimension only—the reward dimension. In the Leventhal and Anderson (1970) design, the child allocator does not have to recall or consider relative work at all to make a self-interest or equality allocation. Self-interest and equality are simple, unidimensional allocation principles within the logical capacity of the preschool child.

A glance at Table 6 should clarify this unidimensional interpretation. The arrows in this table link the objects or concepts to be compared by the reward allocator. The literature suggests that a 4-year-old, for example, can compare the outcomes of Persons A and B to determine whether they are equal or which is larger. Also, the 4-year-old can compare the inputs of Person A and Person B. Thus, the allocation cognitions of the unidimensional child involve only the observation that outcomes or inputs are the same or different for different persons.

Ordinal equity theory in children under 13 years of age. The middle school child is usually capable of preserving ordinal relationships on two or more dimensions for comparison. In other words, the ordinal equity child is able to compare the comparisons. In terms of Table 6, the child notes first that Person A's outcomes are greater than Person B's outcomes and that Person A's inputs are greater than Person B's inputs. But then the child goes on to compare the relationships to see whether or not they are consistent. If A's inputs are greater than B's, but B's outcomes are greater than A's, then equity is violated. In essence, the child is comparing ranks between people on two dimensions, a comparison of abstractions. (The capacity to hold relationships in mind for comparison is an attribute of Piaget's concrete operational thought. Piaget [1964] discussed this capacity as an element of the ability to seriate, or rank, objects on some dimension such as size or number. To seriate sticks, for example, Piaget argued that it is necessary to simultaneously realize that $A < B$ and $B < C$.)

Ordinal equity, in the allocation context, is nothing new. Indeed, Homans's (1961) distributive justice concept, which he applies to adults, is an ordinal allocation rule:

> As a practical matter, distributive justice is realized when each of the various features of his investments and his activities, put into rank order in comparison with those of other men, falls in the same place in all the different rank orders. (p. 264)

As far as ordinal equity with children is concerned, it may have two substages. The first is ordinal equity, as just described, in which two ordinal comparisons are compared ordinally to see if the ranks differ. The second, perhaps beginning around 9 years of

age, could be called *impending interval equity*. At this point, the child may come to believe that inequity exists, even though Person A has greater outcomes and inputs than Person B. This feeling of inequity would occur when A's inputs were much larger than B's but his outcomes were only a little larger. Piaget, Grize, Szeminska, and Vinh Bang (1968) have explored this onset of measurement in the physical domain; but it has not been explored in allocation research.

Proportional Equity Theory in Adolescents

Formal operational thinkers—normally persons of adolescent age or older—are capable of the proportional thought implied by Adams (1965). Adams's theory implies that the ratios that are compared for proportionality consist of the inputs (or work) and the outcomes (or rewards) of a single person:

$$\frac{\textit{Reward A}}{\textit{Work A}} = \frac{\textit{Reward B}}{\textit{Work B}}.$$

This formulation causes certain cognitive difficulties because the numerator and denominator are expressed in different units. However, the formally equivalent proportion, in which a dimension rather than a person is expressed in the ratio, is cognitively simpler:

$$\frac{\textit{Work A}}{\textit{Work B}} = \frac{\textit{Reward A}}{\textit{Reward B}}.$$

It is probably comprehended earlier by the adolescent. When more than two persons are being compared, the simplier formulation can be modified to take the form

$$\frac{\textit{Work A}}{\textit{Work A} + \textit{Work B} + \textit{Work C}} = \frac{\textit{Reward A}}{\textit{Reward A} + \textit{Reward B} + \textit{Reward C}}.$$

We suggest that subjects cognitively assess each person in terms of whether his work, as a proportion of all the work, is equivalent to his reward, as a proportion of all the reward. Hook (1978) found this to be the way 13-year-old proportional thinkers made allocations; and other than for Homans, it is the formulation adopted by the allocation theorists who preceded Adams (see Patchen, 1961; Sayles, 1958). It is also consistent with work by integration theorists (Anderson & Farkas, 1975) on the relative accuracy of prediction of the three equity equations just mentioned.

Group Reaction Time Distributions and an Analysis of Distribution Statistics

Roger Ratcliff
Dartmouth College

A method of obtaining an average reaction time distribution for a group of subjects is described. The method is particularly useful for cases in which data from many subjects are available but there are only 10–20 reaction time observations per subject cell. Essentially, reaction times for each subject are organized in ascending order, and quantiles are calculated. The quantiles are then averaged over subjects to give group quantiles (cf. Vincent learning curves). From the group quantiles, a group reaction time distribution can be constructed. It is shown that this method of averaging is exact for certain distributions (i.e., the resulting distribution belongs to the same family as the individual distributions). Furthermore, Monte Carlo studies and application of the method to the combined data from three large experiments provide evidence that properties derived from the group reaction time distribution are much the same as average properties derived from the data of individual subjects. This article also examines how to quantitatively describe the shape of reaction time distributions. The use of moments and cumulants as sources of information about distribution shape is evaluated and rejected because of extreme dependence on long, outlier reaction times. As an alternative, the use of explicit distribution functions as approximations to reaction time distributions is considered.

Despite the recent popularity of reaction time research, the use of reaction time distributions for both model testing and model development has been largely ignored. This is surprising in view of the fact that properties of distributions can prove decisive in discriminating among models (Sternberg, Note 1) and can falsify models that quite adequately describe the behavior of mean reaction time (Ratcliff & Murdock, 1976).

Two methods have been used to obtain distributional or shape information. One method, advocated by Sternberg (1969; Sternberg, Note 2), is to use moments and cumulants to describe distribution shape without assuming any particular reaction time distribution function. A second method, used by Ratcliff and Murdock, is to assume an explicit distribution function and use the parameters of this distribution to provide information about shape. Both these methods are unattractive because they require 5 to 10 times the number of observations usually collected in an experiment. For example, to fit an explicit function such as a gamma distribution to experimentally obtained reaction times, a minimum of about 100 observations per subject per condition are required for reliable convergence of fitting procedures and stability of parameter estimates. Similarly, to obtain stable estimates of higher moments, several thousand observations per condition are typically required. The necessity for a large number of observations becomes a particular problem in experimental endeavors in

This research was supported by Grant APA 146 from the National Research Council of Canada and Grant OMHF 164 from the Ontario Mental Health Foundation to B. B. Murdock, Jr.

I would like to thank Ben Murdock for his support, help, and criticism. I also wish to thank David Andrews for many useful suggestions and Gail McKoon for help in making the article somewhat understandable.

which the test materials used require a great deal of time and effort for construction (e.g., paragraphs; Kintsch, 1974). For such research programs, it would take years to construct enough materials to allow application of either of the two distributional methods.

In the first part of this article, I present a method for combining data from individual subjects to produce group reaction time distributions based on as few as 10 observations per subject cell. To form group distributions, reaction times for each subject are organized in ascending order, and quantiles are calculated. The quantiles are then averaged over subjects to give group quantiles (Vincent averaging; Vincent, 1912). From the group quantiles, a group reaction time distribution can be constructed. This group distribution method averages over individual subjects' data in a way that retains shape information, and this is demonstrated in three ways: First, it is shown that for certain distributional forms (exponential, Weibull, and logistic), Vincent averaging of individual distributions of a particular form with different parameters results in a group distribution of the same functional form. Second, a distribution that has been used to describe reaction time data (Ratcliff & Murdock, 1976) was used in Monte Carlo studies to generate reaction times that were then combined according to Vincent's method. With 20 reaction times per pseudosubject, the group distributions generated by this method have the same form as the distribution used to generate the data. Third, the method was applied to the combined data from three large recognition memory experiments that used the study–test procedure (Ratcliff & Murdock, 1976), with about 120,000 observations in total. It is shown that parameters derived from fitting a distribution function (used by Ratcliff & Murdock, 1976) to the group distribution are the same as averages of the parameters derived from fitting the function to individual distributions.

In the second part of the article, I critically examine the use of moments and cumulants for describing distribution shape. The stability of moment and cumulant estimates is examined first by calculating sampling standard deviations and second by observing the stability of estimates when outlier reaction times are trimmed from the distribution. In addition, the use of empirical distribution functions to provide information about distribution shape is examined.

The notion of shape can be defined in different ways. Mosteller and Tukey (1977, chap. 1) defined shape as what is left when location (position of the distribution on the abscissa) and scale (the scale on the abscissa) are given up. They showed that shape cannot be defined in terms of the mathematical form of the distribution function. For example, the family of beta density functions have the same functional form, but differ widely in shape (Mosteller & Tukey, 1977, p. 9). However, one of the most striking properties of reaction time distributions is that in the main they all have roughly the same shape, being skewed to the right. (Occasionally normality is claimed for simple reaction time distributions, but this is probably not true [Mosteller, & Tukey, 1977, p. 11].) The group distribution method is concerned with averaging over subjects while preserving distribution shape, which for distribution functions shaped like reaction time distributions often turns out to be much the same as preserving the functional form, as is shown later.

Reaction time distributions have been examined in some detail with respect to specific mathematical models. McGill (1963) provided an excellent summary of work prior to 1963 and presented formal theory for a number of latency models. Green and Luce (1971) have used transform techniques in conjunction with a specific decision model to decompose reaction time distributions into component distributions, and this method of decomposition has been used in testing a neural timing theory (Luce & Green, 1972). Hohle (1965), Snodgrass (1969), and Snodgrass, Luce, and Galanter (1967) have fitted various empirical distributions to choice and simple reaction time data. None of this work, however, provides a general approach to obtaining distributional or shape information.

Before proceeding to a discussion of methods, I briefly illustrate potential uses of distributional information by listing predictions made by four models about distribution shape. First, serial scanning models of item recognition that assume independent and identically distributed comparison stages predict (by the central limit theorem) that as the number of comparison stages increases, the skewness of the reaction time distribution will decrease, and so the distribution will become more normal in shape. Second, the Atkinson and Juola (1973) model of item recognition predicts bimodal reaction time distributions. Third, the multiple observations model for signal detection (Pike, 1973) predicts that when the count criteria increase, mean latency will increase and skewness will decrease. Fourth, the random walk model for item recognition (Ratcliff, 1978) predicts that as the relatedness between probe item and memory item decreases, the mode and mean of the reaction time distribution will diverge. These examples are meant only to indicate the kinds of predictions that models produce and thus the kinds of tests for which distributional analyses prove useful.

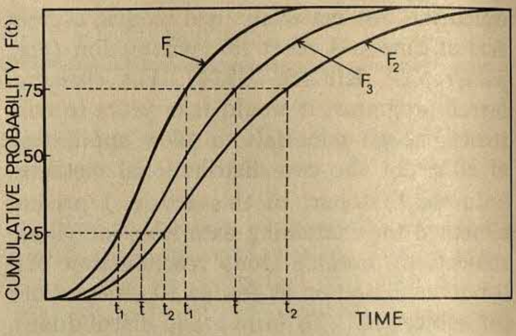

Figure 1. An example of Vincent (1912) averaging applied to cumulative distribution functions; $F_3(t)$ is the Vincent average curve of the curves $F_1(t)$ and $F_2(t)$, and $\bar{t}$ is the average of t_1 and t_2.

Group Reaction Time Distributions

In experimental psychology it is usual to generalize findings across subjects. Often this is done by averaging data over subjects and making inferences based on the group data. Unfortunately, if raw reaction times from several subjects were simply combined to obtain distributional information, then the group distribution would not reflect the shape of the individual distributions. As an illustration, consider two subjects' unimodal reaction time distributions with respective means of 500 msec and 900 msec, each with 100-msec standard deviations. Simply combining the data would give a bimodal distribution, and this would not reflect the unimodal, individual distributions.

If there are enough observations per subject cell, then the best way to obtain distribution information is to derive distributional or shape estimates for each subject cell and then average these estimates over subjects. For example, Ratcliff and Murdock (1976) have used the function arising from the convolution of the normal $[N(\mu,\sigma)]$ and exponential $[g(t) = (1/\tau)e^{-t/\tau}]$ distribution functions, $f(t)$, as an empirical summary of the shape of individual subjects' reaction time distributions (see also Hohle, 1965). Generalization was then accomplished by finding the average of each convolution parameter (μ, σ, and τ) across subjects. The expression for the convolution is

$$f(t) = \frac{e^{-[(t-\mu)/\tau]+\sigma^2/2\tau^2}}{\tau(2\pi)^{\frac{1}{2}}} \times \int_{-\infty}^{[(t-\mu)/\sigma]-\sigma/\tau} e^{-y^2/2}dy. \quad (1)$$

In a similar vein, Sternberg (Note 2) found four cumulants of distributions for each subject cell and generalized across subjects by averaging each cumulant across subjects for each cell. However, the usual experiment does not provide the number of observations required for these methods. Distribution information can still be obtained by using the group distribution method.

Group Distribution Method

The method is very similar to the technique devised by Vincent (1912) for plotting learning curves. In Vincent's procedure, each individual's learning curve is divided into equal fractions (number of trials to 10%, 20%, . . .), and performance of subjects at each fraction is summed and then

averaged. Figure 1 shows an example of this "Vincentizing" procedure applied to two cumulative reaction time distributions to produce the average cumulative distribution. In essence, reaction times at a fixed probability level (quantile) from the two distributions are averaged to give the mean quantile reaction time.

The procedure for estimating the sample quantiles is carried out as follows: Each subject's reaction times $T_1, \ldots, T_n$ are arranged in ascending order of magnitude: $T_{(1)}, T_{(2)}, \ldots, T_{(n)}$, where $T_{(i)}$ is the ith order statistic (David, 1970; Sarhan & Greenberg, 1962). From these ordered reaction times, q sample quantiles are estimated for each subject's data (generally with $q < n$). Each quantile is then averaged across subjects to give a mean $m\%$ sample quantile. In detail, suppose there are n observations for the first subject and one wishes to obtain q quantiles ($q < n$). Then for each subject, each ordered latency $T_{(i)}$ is replaced by q equal latencies, $T_{(i)}$, thereby forming a list that is the length of the product of q and n: $T_{(1)}, T_{(1)}, \ldots, T_{(1)}, T_{(2)}, T_{(2)}, \ldots, T_{(2)}, T_{(3)}, \ldots$. To calculate the first quantile, the first n latencies are summed and divided by n; the second quantile is given by the sum of the next n latencies divided by n, and so on. This procedure is equivalent to simple linear interpolation. For example, if there were 14 responses and deciles were to be calculated, the first decile would be given by $(10/14)T_{(1)} + (4/14)T_{(2)}$, the second by $(6/14)T_{(2)} + (8/14)T_{(3)}$, the third by $(2/14)T_{(3)} + (10/14)T_{(4)} + (2/14)T_{(5)}$, and so on. When the quantiles have been calculated for each subject, each quantile is averaged across subjects to give group quantiles.

Group distribution histograms can be constructed by plotting quantiles on the abscissa and then constructing rectangles between adjacent quantiles such that all the rectangles have equal areas, as in Figure 2.

Several points about this method need discussion. First, the group distribution should be thought of as representing the distribution of the average subject, just as average reaction time represents the reaction time of the average subject. Second, order statistics are biased estimators of quantiles

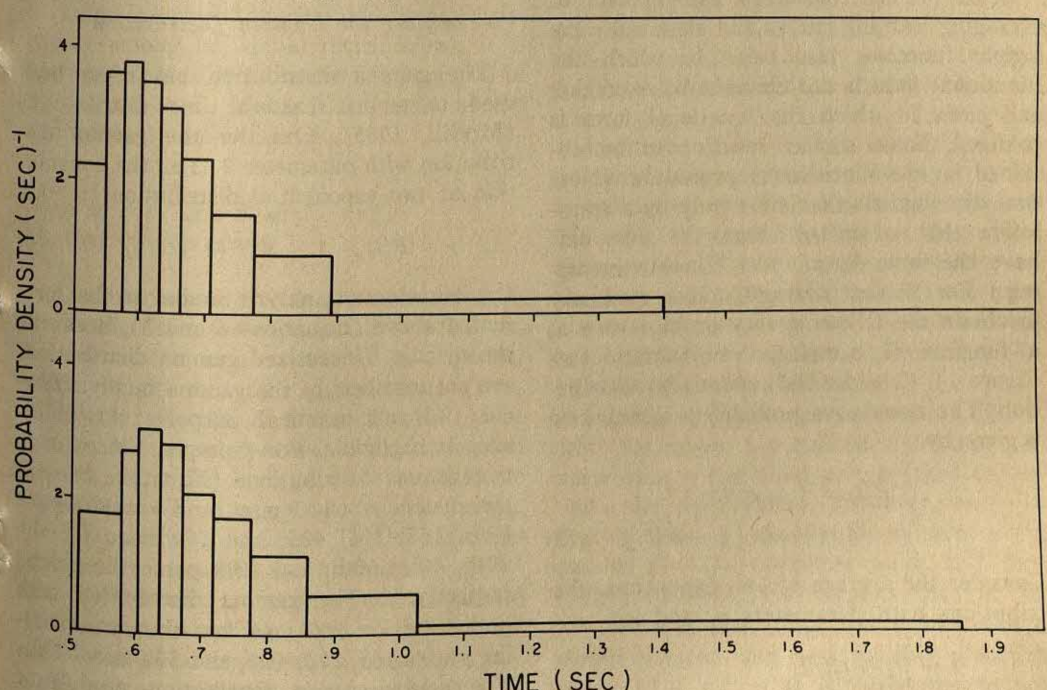

Figure 2. Two sample group reaction time distributions for 10% quantiles. (Data are from the three experiments reported later and represent correct rejections in Output Blocks 1 and 4.)

(David, 1970, chap. 4). However, if there are roughly the same number of observations for each subject cell and if the individual distributions for each subject cell have approximately the same shape, then the group distribution will reflect the same bias as the individual distributions. Third, it is a general problem that the shape of a group curve may not reflect the shape of individual curves. This problem was considered in great detail in the mid-1950s (Bakan, 1954; Estes, 1956; Hayes, 1953; Sidman, 1952; Spence, 1956). The general conclusion reached was that group curves often do not reflect the form of individual curves but that if care is taken group curves can be used to test hypotheses about individual curves. The next two sections examine this problem with respect to the Vincent averaging procedure, and later sections examine the problem with respect to Vincent averaging of reaction time distributions.

Some Exact Results for Vincentized Curves

Estes (1956) considered the problem of averaging learning curves and classified some simple functions into cases in which the functional form is not changed by averaging and cases in which the functional form is changed. Some similar results can be obtained for the Vincentizing procedure. (Note that distributions that differ only by a translation that is shifted along the time axis have the same form under Vincent averaging.) For Vincent averaging, it is necessary to obtain the following relationship: time as a function of cumulative probability (see Figure 1). Consider the exponential distribution. The cumulative probability distribution is given by

$$F(t) = 1 - e^{-t/\tau};$$

$$\therefore \qquad t = -\tau \ln [1 - F(t)]. \qquad (2)$$

Consider the average of two exponential distributions with parameters τ_1 and τ_2:

$$\bar{t} = (t_1 + t_2)/2$$

$$= -\frac{(\tau_1 + \tau_2)}{2} \ln [1 - F(t)]. \qquad (3)$$

Thus the "Vincentized" average of n exponential distributions is exponential with parameter $\Sigma^n{}_{i=1}\ \tau_i/n$. For the Weibull distribution,

$$F(t) = 1 - e^{-(t/\tau)^\gamma},$$

with fixed parameter γ; the Vincentized distribution is also a Weibull distribution, with parameter $\Sigma^n{}_{i=1}\ \tau_i/n$. Similarly, for the logistic distribution,

$$F(t) = 1/[1 - e^{-(t-\alpha)/\beta}];$$

the Vincentized distribution is also logistic, with parameters $\alpha = \Sigma^n{}_{i=1}\ \alpha_i/n$ and $\beta = \Sigma^n{}_{i=1}\ \beta_i/n$. Although normal distributions will not give exactly a normal distribution when Vincentized, the logistic distribution is a very good approximation to the normal distribution, so that any differences are probably very small. It should be noted that the exponential, Weibull ($\gamma > 1$), and logistic distributions have been postulated (or are very similar to distributions that have been postulated) to represent the distributions of processing stages in various models.

Vincentizing the Gamma Distribution

The gamma distribution has often been used to model reaction time distributions (McGill, 1963). Consider the gamma distribution with parameter 2 (i.e., the convolution of two exponential distributions):

$$F(t) = 1 - e^{-t/\tau}(1 + t/\tau). \qquad (4)$$

By following an analysis similar to that presented above (Equations 2 and 3), it can be shown that Vincentized gamma distributions are not members of the gamma family. However, for all practical purposes the difference is negligible. For example, Vincentizing two gamma distributions (Equation 4) with parameters $\tau = 100$ msec and $\tau = 300$ msec gives 165, 276, 405, and 599 msec for the 20th, 40th, 60th, and 80th percentile points, respectively. The gamma distribution with parameter $\tau = 200$ msec has the corresponding points 165, 275, 404, and 599 msec. Thus Vincentizing gamma distributions produces a distribution that is very similar in shape to another gamma distribution.

The examples so far have all considered the Vincentizing of combinations of distributions that differ from one another only in the parameters that have dimensions of time, that is, parameters that represent the duration of some processing stage. There are other parameters that do not represent durations, for example, the number of convolved exponential distributions in the gamma distribution and γ in the Weibull distribution. Vincentizing distributions that vary in these parameters may not produce a distribution that is anything like the average subject's distribution. An extreme example of a distribution with this problem is the beta distribution. Mosteller and Tukey (1977, p. 9), in considering the problems involved in dealing with distribution shape, presented a figure showing the family of beta distributions to illustrate that even distributions belonging to the same family can differ widely in shape. From the graphs presented in Mosteller and Tukey, it can be seen that very serious problems may be involved in averaging across distributions of widely differing shape. To decide whether Vincent averaging will work in cases in which distribution shape varies widely among individual distributions, it is probably best to test the method as above or to perform some Monte Carlo tests as described in the next section.

Some Monte Carlo Studies Using the Convolution Model

The distribution that is the convolution of the normal and the exponential distributions (Equation 1) has been used as an empirical model of reaction time distributions (Ratcliff, 1978; Ratcliff & Murdock, 1976). The fits of the convolution to the data are good enough to make it reasonable to use the convolution in Monte Carlo studies testing the Vincentizing procedure. The Monte Carlo studies are presented to illustrate the use of the Vincentizing procedure under optimal conditions in which the form of the individual distributions is known.

To use the Monte Carlo method it is necessary to generate a random number from the convolution of normal and exponential distributions. This can be accomplished by simply adding a random number generated from the normal distribution and a random number generated from the exponential distribution. Most computer systems have a random number generator that will produce random numbers between 0 and 1 from a rectangular distribution. Equation 2 can be used to produce exponentially distributed random numbers (with parameter τ) by substituting rectangularly distributed random numbers (RND) for $F(t)$. Normally distributed random numbers with mean μ and standard deviation σ can be obtained using the method proposed by Box and Muller (1958), as shown in Equation 5:

$$t = [-2\,ln(RND)]^{\frac{1}{2}} \cos(2\pi RND)\sigma + \mu. \quad (5)$$

Each Monte Carlo study consisted of several experiments (typically 50 to 100). In each experiment, 20 reaction times were obtained from each of 40 pseudosubjects. The 20 reaction times were arranged in ascending order and then averaged across subjects to give group 5% quantiles. The convolution model was then fitted to the set of 5% quantiles (5%, 10%, 15%, . . .) using the maximum likelihood method described in Ratcliff and Murdock (1976). Note that the quantile reaction times are derived from random variables; and so, strictly speaking, the parameter estimates do not have the nice properties of maximum likelihood estimators. However, estimating parameters this way is no worse than estimating parameters by, say, the least squares method, because the quantile reaction times are not independent and the expression being fitted is nonlinear. Results are shown in Table 1.

In general, the parameters μ and τ derived from fits to the Vincentized distribution are very close to the input values (used to generate the pseudodata). However, as τ increases (from .05 to .30), the value of σ (input value = .04) becomes more and more underestimated. This suggests that in any practical use, the value of σ is likely to be underestimated and less reliable than the values of μ and τ. It is interesting to note that the values of s_μ, s_σ, and s_τ are very close to the asymptotic variance estimates for the

Table 1
Monte Carlo Studies for the Convolution Model

Input parameter			Fitted parameter and standard error estimate						No. of experiments
μ	σ	τ	μ	s_μ	σ	s_σ	τ	s_τ	
.50	.04	.05	.5005	.0004	.0371	.0003	.0486	.0005	65
.50	.04	.15	.4996	.0004	.0325	.0004	.1498	.0006	101
.50	.04	.30	.5016	.0008	.0275	.0007	.2955	.0015	58/109[a]
.50	.10	.50	.5002	.0014	.0749	.0012	.4994	.0024	98
.50	.04	.055–.250[b]	.4980	.0006	.0314	.0006	.1545	.0012	52

Note. s = the standard error in the mean $([\Sigma(X_i - M)^2/n(n-1)]^{\frac{1}{2}})$.
[a] 51 of the 109 experiments terminated with the fitted value of σ equal to zero.
[b] The 40 pseudosubjects had different τs, ranging from .055 to .250 in steps of .005, M = .1525.

convolution model presented in Ratcliff and Murdock (1976, Table 2). The last series of Monte Carlo experiments presented in Table 1 used 40 pseudosubjects with different τ values. The value of the average Vincentized τ was almost equal to the average input τ. This result shows that the Vincent-averaging properties of the exponential distribution carry over to parameter τ of the convolution to a good approximation.

These Monte Carlo studies show that application of Vincent's (1912) procedure to the distribution that is the convolution of normal and exponential distributions, a distribution that fits response latency distributions reasonably well, introduces little bias into parameter estimates.

Practical Test of the Group Distribution Method

To provide a stable data base for a practical examination of the method, three experiments (with four subjects per experiment) were combined, giving about 120,000 reaction times in total. The experimental procedure was the study–test recognition memory paradigm. The experiments have been reported as Experiments 2 and 1 in Ratcliff and Murdock (1976) and Experiment 1 in Ratcliff (1978); they are referred to here as Experiments 1, 2, and 3, respectively. A brief description of the study–test procedure is presented here; for further details, consult Ratcliff and Murdock.

In each of the three experiments, a list of study words was presented to the subject at about one word per sec, followed by a test list containing all the study words plus an equal number of new words in random order. For each word in the test list, the subject had to respond on a 6-point confidence scale ranging from *sure old* to *sure new*. Study lists were 16 words long, and test lists were 32 words long, except in Experiment 1 in which the study list contained 15 words and the test list 30 words. The list words were randomly sampled from the Toronto word pool (Okada, 1971). Repetitions of words were prohibited until at least two lists had intervened. The test list was self-paced, and words stayed in view until a response was made. In Experiment 1 and Experiment 3 rate of presentation of the study lists was varied between .5 sec and 2 sec per item. Effects on mean reaction time were small, on the order of 40 msec. In the following analyses, data from the different presentation-rate conditions are combined; this does not significantly affect distribution shape.

The experimental data are classified into eight cells, four output- or test-position blocks (2–8, 9–16, 17–24, and 25–32) for high-confidence hits, and the same four output-position blocks for correct rejections. (The first output position is excluded because this reaction time is typically several hundred msec slower than other reaction times in the test list.) This division of data gives about 1,200 observations for each of the 96 subject cells (12 subjects × 8 cells).

It was noted earlier that to test the group distribution method, properties derived from

4	538	49	225	532	48	229

Note. Data are truncated at 5 sec and at 2 sec.

the group distribution must be compared with the averages of the properties derived from the individual distributions. The properties chosen for comparison were the parameters of the convolution model, μ, σ, and τ (see Equation 1). Estimates of these parameters were obtained from the group distributions (2% quantiles) for each of the eight cells by fitting the convolution model to the group quantiles. (See Ratcliff & Murdock, 1976, for the maximum likelihood method of fitting.) Estimates of the parameters were obtained from the individual subject distributions by first fitting the convolution to each subject's distribution and then averaging the obtained estimates over subjects. The estimates given by the two procedures can be compared in Table 2: For two conditions each, estimates with latencies longer than 5 sec eliminated and estimates with latencies longer than 2 sec eliminated. It can be seen that the two procedures give almost identical estimates of the convolution parameters. This supports the claim made earlier that the group distribution provides an unbiased summary of individual data.

Figures 2, 3, and 4 show some sample data. Figure 2 shows group reaction time distributions for correct rejections in Output Block 1 and in Output Block 4. Figure 4 shows group reaction time distributions and fits of the convolution model for hits in all four output blocks. The Figure 2 distributions are based on 20% quantiles, the Figure 4 distributions on 2% quantiles. Figure 3 shows some sample fits of the convolution model to reaction time distributions for individual subjects for hits in Output Block 1. Although the chi-squares are often significant (because the large numbers of observations make the

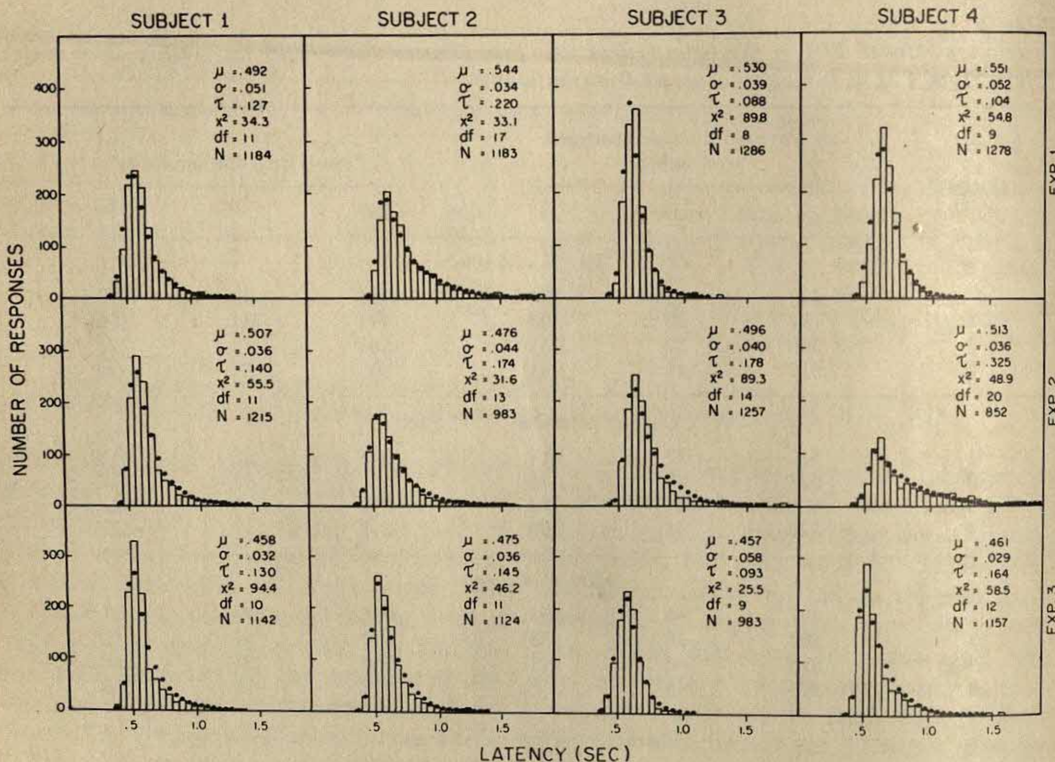

Figure 3. Empirical and fitted latency distributions for hits, Output Block 1. (Exp. 1 = Experiment 2, Ratcliff and Murdock, 1976; Exp. 2 = Experiment 1, Ratcliff and Murdock, 1976; Exp. 3 = Experiment 1, Ratcliff, 1978.)

chi-square a very powerful test), the fits are actually quite good; certainly the convolution captures the overall shape of the distribution. Problems associated with truncation and outliers are discussed in the section entitled Moments and Cumulants.

Probability Mixtures of Distributions and Bimodality

Occasionally a model is developed that predicts bimodal reaction time distributions arising from a probability mixture of processes (e.g., Atkinson & Juola, 1973). The question arises as to whether Vincent averaging across bimodal distributions from individual subjects will produce a bimodal group distribution. In general, the answer is only under conditions in which the proportion of responses in each process is approximately the same across subjects. For example, Figure 5 shows the Vincent average cumulative distribution function for two distribution functions, each of which is a probability mixture of two processes. One distribution has a 25%–75% combination, and the other has a 75%–25% combination. The resulting group distribution is trimodal (i.e., has four points of inflection) and certainly does not reflect the bimodal nature of the individual distributions. In situations in which bimodality and probability mixtures of processes are expected, it is probably best to collect several hundred latencies per subject condition and investigate the individual latency distributions.

Moments and Cumulants

Moments have been used for many years to determine the shape of frequency curves either through skewness and kurtosis indices or by explicitly determining the frequency curve within Pearson's (cited in Elderton,

1906; Elderton & Johnson, 1969) system. Recently moments and cumulants have been used in the additive factor method for analysis of stage models (Sternberg, 1969; Sternberg, Note 2). In this section, three related problems in the use of moments and cumulants as sources of shape information are discussed. These problems are first that the variance associated with estimates of these measures is extremely large, second that the measures are very sensitive to outliers, and third that the measures give information about a part of the frequency curve that is of little theoretical interest.

To investigate the variability of moments and cumulants, expressions for moments and cumulants and their standard deviations must be derived. These expressions are derived for an explicit distribution function to allow estimation of numerical values. The convolution of normal and exponential distributions is chosen because it approximates the shape of reaction time distributions.

Moments are defined as follows (Kendall & Stuart, 1969):

$$\mu'_1 = \int_{-\infty}^{\infty} t f(t) dt;$$

$$\mu_i = \int_{-\infty}^{\infty} (t - \mu'_1)^i f(t) dt, \quad \text{for} \quad i > 1.$$

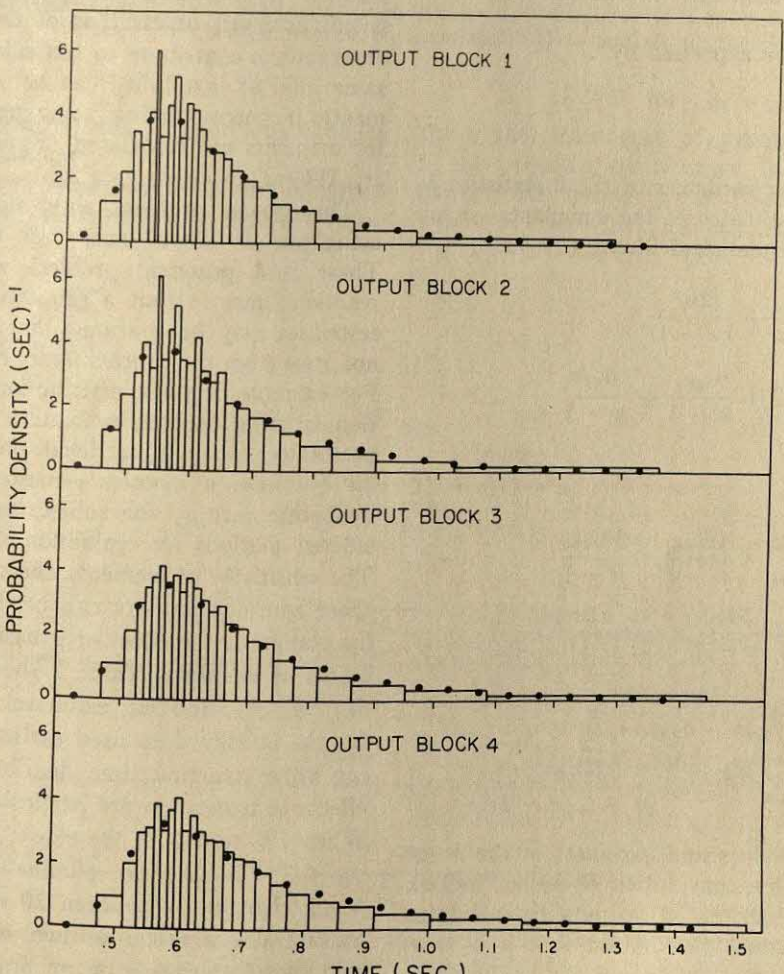

Figure 4. Group reaction time distributions for 2% quantiles for hits together with fits of the convolution model to the group distributions.

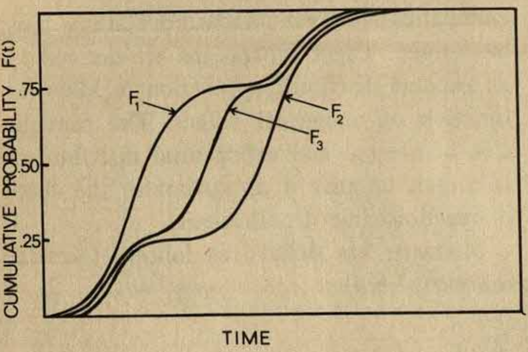

Figure 5. An example of group averaging of two bimodal distributions; $F_1(t)$ has 75% of the probability density in the first peak of the density function, $F_2(t)$ has 25% of the probability density in the first peak, and the resulting Vincent (1912) average distribution $F_3(t)$ is trimodal.

Cumulants are expressed by

$$\kappa_i = \mu_i, \quad \text{for} \quad i \leq 3;$$
$$\kappa_4 = \mu_4 - 3\mu_2^2.$$

The sampling variances of the k statistics k_i (unbiased estimates of the cumulants κ_i) are given by Kendall and Stuart (1969):

$$\text{var}\,(k_2) = \frac{\kappa_4}{n} + \frac{2\kappa_2^2}{(n-1)},$$

$$\text{var}\,(k_3) = \frac{\kappa_6}{n} + \frac{9\kappa_4\kappa_2}{n-1} + \frac{9\kappa_3^2}{n-1} + \frac{6n\kappa_2^3}{(n-1)(n-2)},$$

$$\text{var}\,(k_4) = \frac{\kappa_8}{n} + \frac{16\kappa_6\kappa_2}{n-1} + \frac{48\kappa_5\kappa_3}{n-1} + \frac{34\kappa_4^2}{n-1} + \frac{12n\kappa_4\kappa_2^2}{(n-1)(n-2)} + \frac{144n\kappa_3^2\kappa_2}{(n-1)(n-2)} + \frac{24n(n+1)\kappa_2^4}{(n-1)(n-2)(n-3)}.$$

Expected values and variances of the k statistics for the convolution of normal and exponential distribution can now be calculated. For the normal distribution, $\kappa_1 = \mu$, $\kappa_2 = \sigma^2$, and $\kappa_i = 0$, for $i > 2$; and for the exponential distribution, $\kappa_i = \tau^i(i-1)!$ To convolve two distributions cumulants are added; so for the convolution of normal and exponential distributions, $\kappa_1 = \mu + \tau$, $\kappa_2 = \sigma^2 + \tau^2$, $\kappa_3 = 2\tau^3$, and $\kappa_4 = 6\tau^4$. To estimate numerical values for cumulants and sampling variances of cumulants, values in the range of those found in Table 2 are used: $\mu = .5$ sec, $\sigma = .03$ sec, and $\tau = .2$ sec. Also, $\sigma^2 << \tau^2$, so that to an accuracy of 1% or 2% it is possible to neglect terms in σ compared with terms in τ. Now some numerical values can be calculated: For $n = 100$, $\kappa_2 = .040 \pm .011$, $\kappa_3 = .016 \pm .012$, and $\kappa_4 = .0096 \pm .0174$; for $n = 1{,}000$, $\kappa_2 = .040 \pm .004$, $\kappa_3 = .016 \pm .004$, and $\kappa_4 = .0096 \pm .0055$. From these values of cumulants and their estimated sampling standard errors, it can be seen that stability in the third and fourth cumulants is not achieved unless tens of thousands of observations contribute to the estimates. The same kind of instability can be seen in moments if corresponding sampling variances for moments are calculated (Kendall & Stuart, 1969).

The second problem with moments and cumulants is their sensitivity to outliers. There is a practical problem with outlier reaction times in that a proportion of these responses may be spurious, that is, they do not arise from the process under examination. For example, suppose distributional information is being used to evaluate a model that postulates a single retrieval process. Then an eyeblink, a moment's inattention, or a deliberate rest by the subject must be considered spurious for evaluation of the model. The sensitivity of moments and cumulants to these spurious outliers can be demonstrated by examining the effect of truncation on estimates of moments. Table 3 shows values of m'_1, m_2, m_3, and m_4, estimates of moments for the latency data used earlier (in obtaining group reaction time distributions). The effects of truncation are particularly striking. When 1% to 4% of the slower responses (2 sec $< T <$ 5 sec) are eliminated, mean latency changes by between 20 and 50 msec, variance by a factor of two, and the third and fourth moments by an order of magnitude. Thus, excluding outliers three or more standard deviations above the mean ($m'_1 +$

3	7.98	15.36	2.42	6.13	15,050	7.53	6.03	.30	.29	14,709
4	8.24	20.26	3.73	10.49	13,587	7.63	6.49	.33	.33	13,192

Note. The values for m'_1 are in units of 10 msec, for m_2 in units of 10^4 msec^2, for m_3 in units of 10^8 msec^3, and for m_4 in units of 10^{11} msec^4; m'_1 is mean latency, m_2 is variance and m_3 and m_4 are the third and fourth moments, respectively.

$3(m_2)^{\frac{1}{2}} < 2$ sec) leads to enormous changes in higher moments.

The extreme sensitivity of higher moments to outliers is well-known, and Figure 6 illustrates the dependence of moments on tails of the frequency distribution. In Figure 6 is plotted the frequency distribution $f(x) = x^{-m}e^{-1/x}/[\Gamma(m-1)]$ for $m = 10.6$, together

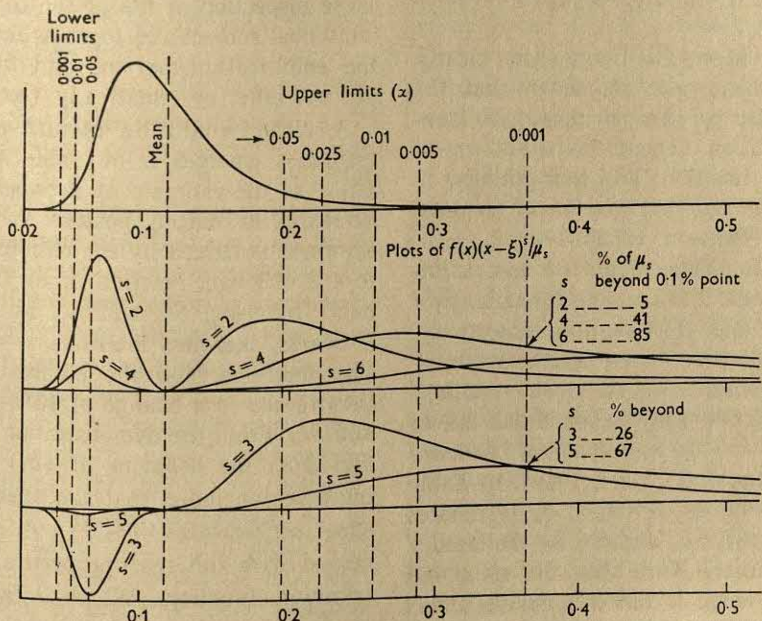

Figure 6. The distribution $f(x) = x^{-m} e^{-1/x}/[\Gamma(m-1)]$, for $m = 10.6$. The lower curves show $f(x) = (x-\xi)^s/\mu_s$, which are the normalized contributions to the moments μ_s, as a function of x, where ξ is the mean. Note. $Sκ_o$ = *(mean − mode)/standard deviation*, where *mean* = m'_1 from Table 3, *standard deviation* = $(m_2)^{\frac{1}{2}}$ from Table 3, and *mode* is calculated from the convolution fits for $T < 2$ sec by setting the first derivative of the probability density function to zero and estimating $t\,[f'(t) = 0]$. $Sκ_e$ = 3 *(mean − median)/standard deviation.*
[a] Cited in Elderton (1906) and Elderton and Johnson (1969).

with the function $c(x) = (x - \xi)^s f(x)/\mu_s$ for $s = 2, 3, \ldots, 6$. Note that

$$\mu_s = \int_{-\infty}^{\infty} (x - \xi)^s f(x)dx,$$

where ξ is the mean. The figure shows clearly the third problem with moments—that the higher moments of an asymmetrical long-tailed distribution depend on the form of the frequency function (and thus outliers) in a region of the tail that may be of no practical interest (Pearson, 1963).

Third and fourth moments are used as indices of skewness and kurtosis through $(\beta_1)^{\frac{1}{2}} = \mu_3/(\mu_2)^{3/2}$ and $\beta_2 = \mu_4/\mu_2^2$, respectively. Pearson has proposed these alternative measures of skewness: $Sκ_o$ = *(mean − mode)/standard deviation* and, to avoid the use of the mode, $Sκ_e$ = 3*(mean − median)/standard deviation* (Kendall & Stuart, 1969). In Table 4 are shown values of $(b_1)^{\frac{1}{2}}$, b_2 (estimates of $(\beta_1)^{\frac{1}{2}}$ and β_2), $Sκ_o$, and $Sκ_e$ for the latency data used earlier. Note that the estimated value of the mode is rather unstable unless a fitted probability density function can be used to locate the mode (Elderton & Johnson, 1969). Thus, the mode used in the calculation of $Sκ_o$ was obtained from the convolution fit to the group data (for $T < 2$ sec) by setting the first derivative of the probability density function to zero. The truncated distribution ($T < 2$ sec) was chosen because inspection of fits of the convolution to individual subject's histograms indicated that the empirical histograms and fitted models did not differ systematically (see Figure 3).

A rather confusing picture of skewness estimates emerges from Table 4. By using $(b_1)^{\frac{1}{2}}$ as the estimate of skewness, skewness decreases as output position increases, and skewness is halved by the elimination of 1% to 4% of longer reaction times. On the other hand, by using $Sκ_o$ and $Sκ_e$ as measures of skewness, skewness increases as output position increases, and the elimination of outliers results in a change of 10%–20% in $Sκ_o$ and $Sκ_e$. From the demonstration in Figure 6 and from the behavior of $(b_1)^{\frac{1}{2}}$ and $Sκ$, it must be concluded that the alternative measures of skewness, $(b_1)^{\frac{1}{2}}$ and $Sκ$, are concerned with different properties of the distribution function. Which measure should be used depends on whether behavior of the central portion of the distribution function (indicated by $Sκ$) or behavior of the extreme tail of the distribution function [indicated by $(b_1)^{\frac{1}{2}}$] is of interest.

I attempted to fit Pearson's (cited in Elderton & Johnson, 1969) system of frequency curves using the moments in Table 3. The curve belongs to Pearson's Type VI class, but the system of frequency curves is not flexible enough to encompass the distributions used in Table 3. The start of a Type VI distribution is at some value, $a > 0$ (Elderton & Johnson, 1969). Calculating the value of a for one set of data in Table 3 gave a value of a around 6 sec, which is beyond the distribution cutoff value. Thus it seems that Pearson's system of frequency curves may not be as flexible as is generally thought (see Patel, Kapadia, & Owen, 1976, for a list of those distributions that belong to Pearson's system and those that do not).

To summarize, moments and cumulants higher than variance have little to offer as sources of shape information about reaction time distributions because of their extreme variability and because they provide information about the extreme tails of the distribution that is of little practical interest. More reasonable sources of shape information are mean, mode, median and standard deviation, together with Pearson's S_{K_0} and S_{K_e} measures of skewness.

A Further Alternative to Moments and Cumulants

Another way to obtain shape information from reaction time distributions is to fit an explicit distribution function and use the parameters of this distribution as a summary of shape. Ratcliff and Murdock (1976) have used the distribution resulting from the convolution of normal and exponential distributions (Equation 1) as an empirical summary of reaction time distributions in memory retrieval paradigms. For simple and choice reaction time paradigms, Snodgrass et al. (1967) have shown that distributions with a rounded mode and exponential tail (e.g., the gamma and so probably the convolution of normal and exponential distributions) are inadequate as descriptions of distribution shape. The distribution they find to give the best fits to their data is the double monomial distribution.

Presenting information about reaction time distributions by providing the parameters of an explicit distribution function (that fits adequately) has the great advantage that it is easy for anyone to reconstruct a distribution (from the formula) that has nearly the same shape as the raw data. This may prove extremely valuable for mathematical modelers who may not wish to invest a large amount of time in obtaining raw data until some initial checks have been carried out. Further examples and discussion of the use of explicit distribution functions as approximations to reaction time distributions can be found in Ratcliff (1978) and Ratcliff and Murdock (1976).

Conclusions and Summary

Information about reaction time distributions can prove very useful in model construction and model testing, but there are few methods available for analysis of distributions. In this article I have presented a method for obtaining group reaction time distributions from experiments in which there are as few as 10 observations per subject cell. The method essentially involves estimating latency quantiles for each subject and then averaging these over the group of subjects. Several distributions were shown to average to give another distribution of the same family with parameters that were the mean of the parameters of the individual member distributions. Several Monte Carlo studies were performed using the distribution that is the convolution of a normal and an exponential distribution, a distribution used to fit reaction time distributions. These studies showed that the parameters derived from the group distributions were the same as the parameters used to generate the individual pseudosubject distributions. Fits of the convolution model to group distributions derived from data combined from three large experiments gave parameters that were almost identical to average parameters from fits to the distributions of individual subjects. The close correspondence between these methods of estimating group averages shows that group distributions provide an excellent summary of

distributional information for the group and do not introduce any systematic bias into the estimate of shape.

Methods of deriving shape information that use moments and cumulants were evaluated, and three major problems were pointed out. First, estimates of the higher moments and cumulants have large standard deviations; for example, 10,000 observations may be needed before the standard deviation on the fourth cumulant is as low as 10% of the size of the fourth cumulant. Second, estimates of moments from data are extremely sensitive to outlier reaction times; the addition of 1% slow responses can change the fourth moment by a power of 10. This problem is particularly severe if an unknown proportion of the slow latencies are spurious, that is, if they are not a result of processes under examination. Third, Figure 6 shows that the third and fourth moments tell one about portions of the distribution that may be of no theoretical interest. It is suggested that the mean and standard deviation together with estimates of median, mode, and Pearson's skewness measures ($S\kappa_0$ and $S\kappa_e$) provide better information about distribution shape. These statistics are adequate, but may not be the most convenient statistics for conceptualizing the distribution or for fitting the distribution to more complex theoretical models. It is further argued that fitting adequate, explicit probability density functions to the observed reaction time distributions may provide more useful summaries of distributional information for researchers involved in mathematical modeling.

Models of Jury Decision Making: A Critical Review

Steven Penrod and Reid Hastie
Harvard University

Several models of jury decision making are reviewed. In each instance the model is described and compared with related models, its assumptions are scrutinized, its fit to normative data is evaluated, and possible revisions and extensions of the model are discussed. Models reviewed include (a) multinomial decision schemes designed to adduce implicit decision rules used in jury decision making, (b) binomial models of jury voting that use simplifying assumptions about jury decision making to assess the impact of explicit decision rules and jury size on verdict distributions, (c) Bayesian models that use normative data to estimate prior probabilities of defendants' "convictability" and juror accuracy, (d) models that assess the relationships among jury size, decision rule, and jury accuracy, (e) models that examine the relationship between juror and jury errors, and (f) a computer simulation that uses simple assumptions about group persuasion and individual differences in jurors' resistance to persuasion to model results from empirical studies of jury decision making.

Until quite recently most of our knowledge about juror and jury behavior has been based on survey research such as Kalven and Zeisel's *The American Jury* (1966) and archival data collected in studies of jury utilization. Within the past decade these data have been supplemented by a growing body of experimental jury research (e.g., Boehm, 1968; Davis, Kerr, Atkin, Holt, & Meek, 1975; Landy & Aronson, 1969; Mitchell & Byrne, 1973; Saks, 1977; Simon, 1967; Simon & Kaplan, 1972; Strodtbeck, James, & Hawkins, 1957; Valenti & Downing, 1975; Padawer-Singer & Barton, Note 1); investigators have used simulated, laboratory juries to explore a wide variety of factors that theoretically affect juror and jury decision making. (For reviews of this research, see Davis, Bray, & Holt, 1977; Penrod, Note 2.)

This research was supported by a grant from the James Marshall Foundation and Grant BNS76-11321 from the National Science Foundation.

The authors would like to thank Dan Stefek for his mathematical and computer programming assistance and Charles Judd and David Kenny for their comments on the manuscript.

Even more recently a number of researchers have begun using survey and experimental data to develop mathematical and computer models of jury decision making, and these models are the focus of this review. The models can be classified into six categories: (a) *implicit-decision-rule* models that use mathematical techniques to determine the implicit rules that juries appear to use in deliberation, (b) simple binomial probability models that use the binomial expansion to mimic the effects of jury size and explicit decision rules on the distribution of jury verdicts, (c) Bayesian models that use Bayesian and binomial models to estimate the prior probability that defendants are guilty and the probability that jurors can accurately detect guilt or innocence, (d) binomial models of juror accuracy and juror satisfaction and their relationship to jury size and decision rules, (e) models of the relationship between juror and jury errors, and (f) a computer model that uses computer-simulated jurors and data from jury studies to explore the relationships among the initial distribution of individual juror opinions, individual differences in persuadability, rates of juror vote changes, coalition sizes within a jury, deliberation times, and the distribution of jury verdicts.

We examine these models giving particular attention to their structure, the plausibility of their underlying assumptions, their fit to available data, and their generalizability.

Implicit Decision Rules

Of the models reviewed here, the one that is most firmly grounded in empirical data—in the sense that it makes the fewest assumptions about jury behavior—is the model developed by Davis and his colleagues (Davis, 1973; Davis et al., 1975; Davis, Kerr, Sussman, & Rissman, 1974). Davis made a fundamental distinction between two types of decision rules that a jury uses: an explicit decision rule such as the requirement that juries reach a unanimous verdict and an implicit decision rule that describes the method by which a jury actually arrives at a verdict. The assumption, of course, is that juries may in fact operate under a decision rule different from the one given to them in a judge's instructions. To determine the implicit rule Davis has used two sources of data: Simon's (1967) study of the insanity defense, in which 30 12-person mock juries deliberated on a housebreaking case and 68 mock juries deliberated on an incest case, and the Davis et al. (1975) and Davis, Kerr, Stasser, Meek, and Holt (1977) studies of a rape case in which student jurors deliberated individually or in 6- or 12-person juries. These last juries were given either a unanimous or a two-thirds rule as their explicit decision rule.

In all of these studies the researchers asked the mock jurors to reveal their personally preferred verdict before deliberation began. Knowledge of the predeliberation distribution votes combined with knowledge of each jury's final verdict allows one to ask, can final verdicts be predicted by applying a particular decision rule to the initial distribution of individual juror votes? Davis (1973) called such a rule an "*implicit* social decision scheme (p. 99)." To determine the implicit decision rule Davis first examined the set of "distinguishable distributions of member preferences within a group (p. 101)." In general, these distributions can be determined by a multinomial expansion in which the set of initial distributions m equals

$$\binom{n+r-1}{r},$$

where n equals the number of mutually exclusive outcomes available to each group member and r equals the number of members. For jurors there are, of course, two possible outcomes (guilt or innocence), so $n = 2$. (When $n = 2$ the appropriate expansion is binomial, and the model is much simpler. A detailed discussion of the binomial expansion can be found in the next section of this article.) For 12-person juries ($r = 12$) there are 13 distinguishable initial distributions:

$$\binom{2+12-1}{12} = 13 = m.$$

These distributions range from 12 votes for guilt and none for innocence (12, 0) to 12 votes for innocence and no votes for guilt (0, 12). Similarly, in a 6-person jury there are 7 possible initial distributions, ranging from (6, 0) to (0, 6).

The question Davis has posed is, given actual data on the frequency of each initial distribution of individual juror verdicts, is there one general decision scheme that will accurately predict the distribution of final jury verdicts? Davis represented various possible decision schemes in the form of an $m \times s$ stochastic matrix in which s corresponds to the available group outcomes (e.g., a verdict of guilt, acquittal, or a hung jury). The entries in the matrix represent the probability that each of the m possible initial distributions will result in one of the s possible group outcomes. Each unique matrix thus represents a distinct decision scheme that may correspond to a jury's implicit decision rule.

Davis et al. (1975) have tested 13 different decision schemes that can be applied to the initial vote distributions for 12-person juries in which final verdicts can be of guilt, innocence, or a hung jury, and Davis, Kerr, Stasser, Meek, and Holt (1977) have tested 15 similar models for 6-member juries. Fortunately, the 3 decision schemes that have provided the best fits can be succinctly characterized verbally. For instance, Decision Scheme 8 from Davis et al. (1975) specifies that if two thirds or more of the jurors agree on a verdict on the initial ballot, this agreement determines the verdict. If two-thirds agreement is not obtained on the first ballot, the decision rule specifies that the jury will hang. For Scheme 7, majorities win,

Table 1
Distribution of Votes for Acquittal on First Ballot and Jury Decisions

	No. of votes for acquittal on first ballot											
	0		1–5		6		7–11		12		Total	% of
Final verdict	*n*	%	*n*	%	*n*	%	*n*	%	*n*	%	*n*	total
Not guilty	0	0	5	5	5	50	37	91	26	100	73	32
Guilty	43	100	90	86	5	50	1	2	0	0	139	62
Hung	0	0	10	9	0	0	3	7	0	0	13	6
Total *n*	43		105		10		41		26		225	
% of total		19		47		4		18		12		100

Note. These data are from Kalven and Zeisel (1966).

otherwise the jury is hung. Scheme 3 reflects a majority persuasion effect in which *persuasion* depends on the size of the initial majority: When 11 or 12 jurors agree (or 5 or 6 jurors agree in a 6-member jury), the verdict is determined; for distributions between (10, 2) and (6, 6) or (4, 2) and (3, 3) in 6-member juries, the juries yield guilty verdicts with probability r_g/r (where r_g is the number of jurors voting for guilt) and not-guilty or hung verdicts with probability $\frac{1}{2}[1 - (r_g/r)]$; and the distributions (5, 7) to (2, 10) [(2, 4) in six-member juries] yield not-guilty verdicts with probability r_{ng}/r and guilty or hung verdicts with probability $\frac{1}{2}[1 - (r_{ng}/r)]$.

Davis (1973) tested 5 different schemes on Simon's (1967) data and found that Scheme 3 made the best predictions for both of Simon's cases. Similarly, he tested 13 decision schemes on his own (Davis et al., 1975) data. The best fitting scheme overall was the two-thirds-majority model (Scheme 8), although other models provided better fits for particular jury sizes and explicit decision rules.

Finally, 15 schemes were tested on the data from Davis, Kerr, Stasser, Meek, and Holt (1977). The study used six-member juries that deliberated with an explicit 4/6 (i.e., four members out of six must agree) decision rule. For these juries a modified two-thirds rule—similar to Scheme 8 except that 75% of (3, 3) juries acquit and 25% hang—best fit the data. Davis et al. concluded that in general juries appear to be operating under an implicit "two-thirds, otherwise hung" decision rule even when the explicit, judge-instructed rule is unanimity.

Davis's approach has been applied by other researchers with similar results. For instance, Saks (1977) studied the effects of explicit decision rule and jury size on the distribution of jury verdicts in two experiments with a total of 85 juries. When Saks tested for implicit decision rules he also found support for Decision Schemes 3 and 8, but he found even stronger support for a power function rule suggested by Latane and Borden (Note 3).

Gelfand and Solomon (1975, 1977) have employed Davis's decision scheme method in their efforts to fit the data on 225 juries supplied by Kalven and Zeisel (1966). (Table 1 reproduces the Kalven and Zeisel data.) Although the first ballot distribution was not given for every possible initial jury split (nonunanimous majorities for guilt and innocence were separately pooled), with minor modifications in Davis's Scheme 3, Gelfand and Solomon estimated the probability of conviction to be .637, of acquittal to be .303, and of a hung jury to be .060—a very close fit to the Kalven and Zeisel data. The Gelfand and Solomon scheme, like Davis's Scheme 3, incorporates a strong majority persuasion effect, but elevates the probability of a hung jury for (10, 2) and (2, 10) initial distributions.

Although these results as a whole support the argument that juries may use something other than their assigned explicit rule, some caution is in order, for the studies reported to date have failed to demonstrate that one particular model consistently makes accurate predictions for all jury sizes and explicit decision rules. Indeed, as Davis et al. (1975) have noted, different implicit rules may apply to different

jury conditions; it may be that different implicit rules apply in criminal and civil cases, that different levels of a defendant's apparent guilt elicit different implicit rules, that complex cases involve yet another type of implicit rule, that different types of judge's instructions vary the implicit rule, and so forth. Only further research can resolve these problems.

An even more subtle and potentially more important methodological problem of the decision scheme analysis must be addressed. To date the evidence suggests that the rate of accurate prediction for individual trials is not reliably high. Most of the tests of implicit rules rely on a comparison of (a) the distribution of verdicts predicted from the application of the decision schemes to initial vote distributions with (b) the final distribution of actual verdicts. But without detailed inspection it is not clear that the final verdicts considered individually are consistent with the predictions made by the various decision schemes. Scheme 8, for instance, might predict an overall distribution of verdicts that would resemble the overall distribution of actual verdicts, but the entries in the stochastic matrix associated with the model might do a poor job of predicting actual verdicts on the basis of initial vote distributions. In other words, the model might fit the aggregated data, but for the wrong reasons. There could be an infinite number of matrices that would predict final distributions identical to those of Scheme 8, but only one of them would make the maximum number of correct predictions. Optimally, one would want to take a model and examine the accuracy of predictions for each entry in the matrix. In the case of Scheme 3, for instance, do 83% of the cases with an initial (10, 2) distribution of votes end up with a guilty verdict, 8% with a hung verdict, and 8% with an innocent verdict? Do 50% of the (6, 6) juries vote for guilt while the other 50% divide evenly to acquit or to hang?

The best fitting Scheme 8 (the two-thirds decision rule) is at least partially defective in this regard. One illustration of its failure is that it does not allow either for reversals of initial majorities (cases in which a minority on the initial ballot ultimately prevails) or for hung juries in cases in which eight or more jurors initially agree. And yet there is ample evidence (e.g., Padawer-Singer & Barton, Note 1) that initial majorities are reversed and that juries can hang even when eight jurors initially agree on a verdict. Some of the models allow for such reversals and provide more sources of hung juries, but unless the rules are fitted to actual outcomes on a jury-by-jury basis rather than on an aggregate distribution of outcomes, it is premature to say that one of the schemes accurately reflects the implicit decision rule.

In fact, the initial results obtained from nonaggregated analyses, although mixed, are on the whole disappointing. Grofman (1976) tested the fit of the two-thirds model on the Davis et al. (1975) and Davis, Kerr, Stasser, Meek, and Holt (1977) data and reported that the results were disappointing. We found that the two-thirds rule predicted the verdicts of 66 of 100 juries in the Kerr et al. (1976) study and 59 of 90 juries in the Davis, Kerr, Stasser, Meek, and Holt (1977) study. In fact, even the best fitting Scheme 15 (the modified two-thirds decision rule) mispredicts 10 of 90 juries. On the other hand, the standard two-thirds model predicted 24 of 25 juries in a study by Grofman and Hamilton (Note 4).

In a later section we discuss some of the factors that may contribute to the poor fit of social decision schemes when they are applied to individual juries, but we note briefly at this point that one major source of the problem may be a by-product of the case that Davis and his colleagues have used in their research. The case is one of rape, and it evokes different reactions from male and female subjects. In both Davis, Kerr, Stasser, Meek, and Holt (1977) and Kerr et al. (1976), approximately 60% of the females voted to convict on the first ballot, while only about 50% of the males voted to convict. During deliberation females changed their votes from conviction to acquittal at rather high rates (in the first study, 18.3% of the females shifted from guilt to innocence compared with a 5.5% shift in the other direction, and males shifted relatively little in either direction). As a result of the higher rate of change to acquittal by females, the overall distribution of verdicts is shifted in the direction of acquittal. Since the social decision schemes typically assume that jurors are equally likely to shift in either direction,

they fail to account for the bias in female juror behavior and are therefore unable to capture the shift to acquittals. Rape cases may be peculiarly susceptible to this sort of phenomenon, and this observation underscores the fact that case type has a significant impact on the deliberation process.

Probabilistic Models

Earlier it was noted that Davis's jury model is built around the binomial expansion. There are other modeling efforts that also make use of the binomial expansion to mathematically evaluate the effects that jury size and decision rule have on the distribution of jury verdicts. These issues are of practical significance and have been the subject of litigation before the U.S. Supreme Court. In 1970 the Court held that six-member juries did not violate a defendant's right to a trial by jury (*Williams* v. *Florida*[1]), and in 1972 the Court held by a narrow margin that nonunanimous juries were constitutional (*Apodaca* v. *Oregon*[2] and *Johnson* v. *Louisiana*[3]). More recently, in *Ballew* v. *Georgia*,[4] the Court, with Justice Blackmun writing the Court's main opinion, cited a number of empirical and theoretical studies to support the holding that juries with fewer than six members violate a defendant's right to a trial by jury.

The court has not yet reached the question of the constitutionality of nonunanimous six-member juries, but since the issue is likely to be pressed in the courts, empirical research and mathematical models directed to the question have acquired additional importance. The mathematical models that are most relevant are the binomial models of Walbert (1971) and Saks and Ostrom (1975). The binomal expansion is a mathematical expression that facilitates the calculation of the probability that a specified number of successes (or failures) will occur in a given number of trials (in the nonlegal sense), where trials are independent of one another and the probability of success is the same for each trial. More simply (using juries as an example), the binomial theorem applies in situations in which there are two possible outcomes (e.g., a juror can vote for either guilt or acquittal), in which there are a fixed number of trials (e.g., there are 12 jurors who must vote), in which outcomes have identical probabilities (e.g., jurors are randomly drawn from a large jury pool in which a certain percentage of jurors will vote for guilt), and in which trials are independent (i.e., a juror's initial judgments of guilt or innocence are independent).

To apply the binomial theorem to the jury it is clear that several assumptions have to be made. First, it must be assumed that all jurors are prepared to vote for either conviction or acquittal; there can be no undecided jurors. It is not clear how often this assumption is violated in practice, but for statistical purposes it must be assumed that all jurors have at least some inclination—however small—toward conviction or acquittal. Second, it must be assumed that jurors are drawn from a larger pool of jurors, in which a certain percentage of the jurors will vote for conviction or acquittal. Finally, it must be assumed that the jurors have not influenced one another's judgments prior to deliberation (this is probably a fairly reasonable assumption in light of the fact that jurors are typically cautioned not to discuss a case or to form an opinion until they have heard all the evidence).

With these assumptions it is possible to use the binomial theorem to determine the probability that a jury will have sufficient votes to convict a defendant on the first ballot:

$$p(G) = \sum_{i=Q}^{n} \binom{n}{i} g^i (1 - g)^{n-i}, \qquad (1)$$

where $p(G)$ is the probability that a jury will produce sufficient votes to convict on the first ballot, n is jury size, Q is the minimum number of votes required to convict (required quorum), g is the probability that a randomly selected juror will vote for guilt, and $1 - g$ is the probability that a randomly selected juror will vote to acquit.

Note that in the case of a unanimous decision rule, $p(G)$ can simply be written as $p(G) = p^n$. The same theorem can also easily be written to determine the probability that a

[4] Ballew v. Georgia, 98 S.Ct. 1029 (1978).

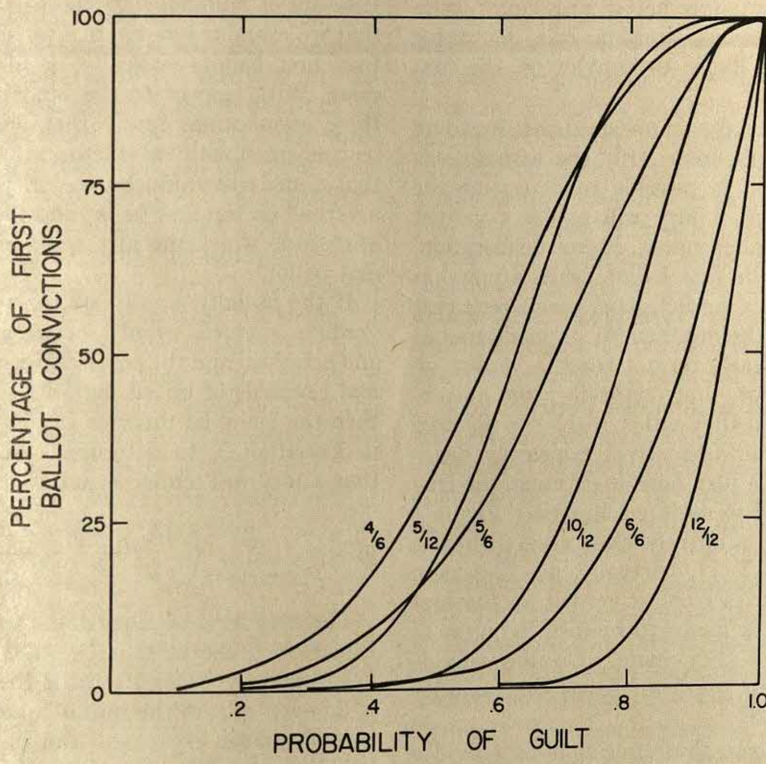

Figure 1. Percentage of first ballot convictions as a function of probability of guilt, according to a single, binomial decision rule model. (Denominator of parameters indicates jury size, and numerator indicates decision rule verdict requirement, i.e., the number of votes needed for a conviction.)

jury will produce sufficient votes to acquit on the first ballot:

$$p(I) = \sum_{i=Q}^{n} \binom{n}{i} g^{n-i}(1-g)^{i}. \qquad (2)$$

Thus, the probability $p(V)$ that a jury will have sufficient votes to produce either a guilt or an acquittal verdict on the first ballot is the sum of the probabilities from Equations 1 and 2:

$$p(V) = \sum_{i=Q}^{n} \binom{n}{i} g^{i}(1-g)^{n-i} + \sum_{i=Q}^{n} \binom{n}{i} g^{n-i}(1-g)^{i}.$$

One can, of course, vary jury size n, the size of the required quorum Q, and the probability that a randomly selected juror will vote for guilt g and use the binomial theorem to determine the probabilities that juries of varying size, drawn from differing jury pools, and who use different decision rules will produce first ballot verdicts for guilt or acquittal (one need only consult appropriate tables of the binomial distribution). Figure 1 summarizes the probabilities of first ballot verdicts for juries of 6 and 12 members who use two-thirds, five-sixths, and unanimous decision rules, where the probability of an individual juror voting for guilt ranges from 0 through 1.0. (Note that the figure also shows the probability of an acquittal—when $1 - g$ is substituted for g, the results are exactly symmetrical.)

Clearly, reductions in the size of the jury and relaxations of the quorum requirements produce similar effects: They heighten the probability that a jury will produce a verdict on the first ballot. Furthermore, if g is in any way an index of a defendant's objective guilt (irrespective of the evidence against the defendant) and juries can accurately detect such guilt on the basis of the evidence presented to them, then it is clear that objectively

guilty defendants fare better with larger juries using a unanimous decision rule, for these juries are less likely to convict on the first ballot.

Thus far we have emphasized that by using the binomial theorem with the assumptions made earlier, it is possible to determine the probability that a jury will render a verdict on the first ballot taken during deliberation. Events after the first ballot, when a jury has failed to reach a verdict, have been a recurrent problem for the mathematical modelers, as most juries clearly do not reach a verdict on the first ballot, but typically continue to deliberate until they either reach the required quorum or find themselves hopelessly deadlocked (when a jury finds itself hung, the trial judge is forced to declare a mistrial). Figure 1 shows that in relatively close cases (where g ranges from .3–.7), virtually no 12-person, unanimous juries reach a verdict on the first ballot. What is likely to happen in juries of this sort? Do they hang? Do they divide evenly in their verdicts? Does the majority tend to prevail?

One answer to these questions is provided by Walbert's (1971) analysis. As one has already seen, Davis's (1973) implicit-decision-rule analysis suggests that initial majorities tend to determine final verdicts; Walbert cited additional evidence to support the claim that deliberation after the first ballot is fundamentally irrelevant to the mathematical analysis. He argued as follows: (a) Small-groups research shows strong majority persuasion effects—with complex judgments minorities tend to conform to the judgments of the majority—that are accentuated by external pressures (such as judges' instructions) and are most evident in group discussions with leadership structures resembling those found in the jury room. (b) Empirical evidence indicates (Kalven & Zeisel, 1966) that majority persuasion operates in about 93% of all cases (minorities prevailed in 3%, and 4% ended with a hung jury). (c) Juries in which jurors initially divide evenly (6 to 6) tend to split evenly for conviction and acquittal (Kalven & Zeisel, 1966).

If one takes these data and assumptions as valid and further assumes that the reported discrepancies (i.e., reversals of initial majorities) are of minimal importance (assumptions that we examine below), it is possible to argue that first ballots basically decide almost all cases. With respect to the binomial theorem, these assumptions imply that one need only be concerned with two factors: the probability that a jury will produce a majority of votes for a verdict on the first ballot and the disposition of cases in which the jury splits evenly on the first ballot.

If the initially evenly split cases yield final verdicts divided evenly between conviction and acquittal and the possibilities of hung cases and reversals of initial majorities are ignored, then the binomial theorem can be modified, as in Equation 3, to determine the probability that a jury will render a guilty verdict:

$$p(G) = \sum_{i=(n/2+1)}^{n} \binom{n}{i} g^i + \frac{g^{n/2}(1-g)^{n/2}}{2}. \quad (3)$$

The first term of Equation 3 is identical to Equation 1, except that Q is the majority of jurors and the second term is the probability of an even split in the initial ballot divided by two. A similar expression can be constructed for the probability of an innocent verdict and is analogous to Equation 2:

$$p(I) = \sum_{i=(n/2+1)}^{r} \binom{n}{i} g^{n-i} + \frac{g^{n/2}(1-g)^{n/2}}{2}. \quad (4)$$

Note that by definition the sum of Equations 3 and 4 is 1.00. Furthermore, in these equations the decision rule is essentially fixed at *majority wins*, and only jury size affects the distribution of guilty and innocent verdicts.

Walbert's decision rule is quite similar to Davis et al. (1975) Scheme 7, except that Walbert eliminated hung juries and assigned evenly divided juries equally to guilt and acquittal. However, where Davis examined results by applying his schemes to initial votes from experimental studies to determine their fit to the data, Walbert made a more general argument. Starting from the assumptions outlined above, Walbert calculated the effect of jury size on the distribution of jury verdicts given a wide range of binomially distributed initial individual votes and using (as in Saks & Ostrom, 1975) varying levels of g (the probability that a randomly selected juror will vote for guilt). Walbert's results indicate that

a reduction in jury size raises the probability of conviction when $g < .5$: For example, when $g = .4$, the use of a 6-member jury increases the probability of conviction from .25 (for the 12-member jury) to .32. And when $g = .2$, the 6-member jury is six times more likely to convict (6% vs. 1%). Parallel results for acquittals are obtained when $g > .5$.

If one makes the additional assumption that g is a fairly reliable indicator of a defendant's "convictability" (i.e., g indexes the weight of the evidence against the defendant), then Walbert's analysis implies that the more convictable defendants are better off with the smaller juries, whereas relatively unconvictable defendants fare better with large juries.

Furthermore, if one regards convictions of relatively unconvictable defendants or acquittals of relatively convictable defendants as errors, it is clear that the larger jury is preferable. Indeed, it can be argued that the optimal pattern of conviction and acquittal would break sharply at $g = .5$. Juries would always convict when g was greater than .5 and acquit when g was less than .5. With these assumptions, optimality would be achieved with infinitely large juries using majority rule. Coincidentally, this optimality rule also maximizes the likelihood that jury verdicts will accurately reflect the attitudes and values of the community from which the jury pool has been drawn (the representativeness of the pool itself would also be a consideration). Indeed, the binomial theorem can be used to determine the probability that a specified number of jurors (analogous to Q) will be selected from a jury pool in which a specified trait (say, race or sex) occurs at a particular rate (analogous to g). Lempert (1975) discussed this representativeness question at length, and in his article he summarized the probabilities that two, one, or no jurors will be selected with the appropriate trait in 6- and 12-member juries for various rates of trait occurrence in the jury pool.

Given the assumptions made in Walbert's (1971) analysis, it is clear that the 6-member jury is inferior to the 12-member jury: It produces more errors and is less likely to represent the population from which it is drawn.

We note, in passing, that there is yet another way to think about g that could provide a quantifiable definition of *reasonable doubt*. If we were to define g_1 as the probability that a randomly selected juror will say that a defendant committed the charged acts beyond a reasonable doubt and g_2 as the probability that a randomly selected juror will vote to convict the defendant under a more-likely-than-not standard of proof, then we could determine a probabilistic value for RD (the additional certainty required for a reasonable-doubt standard) such that $RD = g_1 - g_2$.

If by empirical methods we found that RD was greater than zero, we could use Walbert's formulation of the binomial decision model to examine the effects of a relaxation in the standard of proof required in criminal cases. If, for example, $g_1 = .6$, $g_2 = .5$, and $RD = .1$, a relaxation from the reasonable-doubt standard to the more-likely-than-not standard would increase the probability of conviction from .5 to .75 in the 12-member jury and from .5 to .68 in the 6-member jury (see Walbert's Figure 1). Similar comparisons can be made for different values of g and RD. In every instance (for $RD > 0$) the relaxation of the standard accentuates the differences in 6- versus 12-member error rates.

To date the empirical evidence regarding the value of RD is mixed. In an experimental study involving a theft case, Cornish and Sealy (1973) found that the probability of a conviction under the reasonable-doubt standard was .50 compared with .51 for the more-likely-than-not standard. Simon and Mahan (1971) asked judges, jurors and, students to rate the chances out of 10 that a defendant committed a crime if convicted beyond a reasonable doubt and if convicted by a preponderance of the evidence. All three groups gave a mean rating of approximately 8.5 out of 10 for reasonable doubt; but whereas judges rated preponderance of the evidence at 5.5, the other two groups gave a rating of 7. Similarly, in Kerr et al. (1976), subjects individually judged a videotaped rape trial using one of three definitions of *beyond a reasonable doubt*. Of the jurors who formed a verdict preference after viewing the trial, 51% of those using a stringent definition (moral certainty), 61.2% of those with no definition, and 66.3% of those using a lax

definition (substantial doubt) voted to convict the defendant. When the subjects rated the probability of guilt associated with the standards, the mean rating for the stringent definition was .87 compared with .83 for the other two definitions. Nagel, Lamm, and Neef (Note 5), using a normative decision theory model, reported that student conviction probability thresholds averaged about .55 for various types of criminal cases. Thus, the preliminary evidence indicates that the standards of proof and the definitions of those standards can affect juror judgments, although perhaps not to the extent intended by the legal system. To date there is little research on the factors that may affect the value of RD: the quality of judges' instructions, differential experience with legal decision making, individual differences in jurors, differences in types of defendants and indictments, differences in available verdict alternatives, and differences in the types of judgments a jury must make (such as resolving issues of eyewitness identification vs. selecting a verdict or determining whether a defendant is guilty or innocent of any offense vs. determining which offense a defendant has committed).

Before leaving Walbert's (1971) model, it may be useful to note the points at which his analysis appears to be on the weakest ground. Unlike Davis, who attempted to account for reversals of initial majorities and hung juries in some of his models, Walbert assumed that these phenomena are unimportant when compared with the strong majority persuasion effects that he found in empirical data such as Kalven and Zeisel's (1966). However, as Gelfand and Solomon (1974) pointed out, it is not clear that Walbert has properly characterized the Kalven and Zeisel data (see Table 1). These data summarized the relationship between initial ballot distributions and final verdicts for 225 criminal cases tried in Chicago and Brooklyn. On close inspection, it turns out that for all cases in which the jury was not evenly divided (6 to 6), the initial majority ultimately prevailed in 91.5% of the cases (compared with Walbert's 93%), and the jury hung in 6.0% (compared with Walbert's 4%). Even assuming that Walbert's characterization of the Kalven and Zeisel data is the best possible, his model fails to account for more than 8% of the total cases (six reversals of majorities and 13 hung juries out of 225 cases), and it is not clear what implications these error cases have for his conclusions about the effects of jury size.

Beyond the question of the model's basic fit, one might want to know whether (and in what ways) cases involving reversals of majorities and hung juries differ from cases exhibiting majority persuasion effects. Intuitively, there is good reason to think that such cases are the most difficult for juries to decide; the evidence is not sufficiently compelling in favor of a guilty or an innocent verdict for jurors to be able to readily agree. In other words, these cases may tend to be the ones in which g is close to .5. Some evidence for the difficulty of such cases is provided by the results from Padawer-Singer and Barton's (Note 1) study of 92 6- and 12-member mock juries that deliberated after viewing a videotaped murder trial. This case was evidently fairly difficult to decide, for the probability that a juror randomly selected from the pool of jurors who viewed the trial would vote for guilt was $\approx .47$. And (summing across 6- and 12-member juries who used both unanimous and nonunanimous decision rules) for the 70 juries with initial majorities for a verdict, the majority prevailed in only 68.6% of the cases, the minority prevailed in 12.9%, and 18.6% were hung. Of the 22 juries that were initially evenly split (6 to 6 or 3 to 3), 54.5% ultimately returned innocent verdicts, 40.9% returned guilty verdicts, and 4.5% returned hung verdicts.

The Padawer-Singer and Barton data suggest that Walbert's model may provide the poorest fit for those cases in which accuracy and representativeness are most critical—the "hard to decide" cases. It would be premature, however, to conclude that the postulated lack of fit for cases with g near .5 undermines Walbert's basic arguments about the effects of jury size on jury accuracy and representativeness, for as long as majorities prevail more often than minorities, larger juries should be preferred to smaller juries.

Bayesian Models

One important question that a researcher might ask about juror performance relates to

the juror's ability to accurately determine a defendant's guilt or innocence. One would like to know how often, under the best of circumstances, jurors and juries accurately determine a defendant's objective guilt or innocence. But of course there is no reliable method of determining objective guilt and innocence. One can only ask how reliable jurors and juries are at the task of assessing guilt and innocence from the evidence presented to them at trial (and we would hesitate to argue that the quality of trial evidence is necessarily related to a defendant's objective guilt).

The models examined thus far do not attempt to evaluate the acuity of jurors, but assume that the best available index of a defendant's guilt is the proportion of jurors in a jury pool who, after hearing all the evidence and testimony, are prepared to vote for conviction. In this section we examine a jury model that uses a Bayesian analysis to determine both the prior probability that a defendant is convictable and the probability that jurors will correctly assess this convictability.

In a series of articles, Gelfand and Solomon (1973, 1974, 1975, 1977) have developed a model based on Poisson's (1837) application of probability theory to jury verdicts. Following Poisson, Gelfand and Solomon began their analysis by suggesting that with adequate data two important parameters can be estimated:

1. T is the probability that before trial an accused is convictable, that is, the proportion of defendants brought to trial who are convictable or the probability that the weight of the evidence will be against a randomly selected defendant.

2. M is the probability that a juror will not vote for the wrong verdict, the probability that a jury will correctly assess and vote with the weight of the evidence against a defendant. (For the purpose of modeling, Gelfand and Solomon assumed that T and M are independent and that M is a common value for all jurors.)

Gelfand and Solomon made it clear that when they wrote about convictability, they were really discussing the standards of indictment and the community standards for conviction that might prevail in a criminal justice system and were not using convictability (or more loosely, *guilt*) to mean objective guilt.

The specification of these two parameters allows for the construction of a mixed binomial expression similar to Equation 1 in which it is possible to determine $W_{n,i}$, the probability that a jury with n members will cast exactly i votes for acquittal on the first ballot; $Y_{n,i}$, the probability that a jury with n members will cast at most i votes for acquittal on the first ballot; $p_{n,i}$, the probability that the defendant is guilty given exactly i votes for acquittal on the first ballot; and $P_{n,i}$, the probability that the defendant is guilty given at most i votes for acquittal on the first ballot, where

$$Y_{n,i} = \binom{n}{i}[TM^{n-i}(1-M)^i + (1-T)M^i(1-M)^{n-i}]; \quad (5)$$

$$W_{n,i} = \sum_{j=0}^{i} Y_{n,j};$$

$$p_{n,i} = \binom{n}{i}TM^{n-i}(1-M)^i/Y_{n,i}; \quad (6)$$

$$P_{n,i} = T\sum_{j=0}^{i}\binom{n}{j}M^{n-j}(1-M)^j/W_{n,i}.$$

Note that Y is the sum of correct and incorrect votes for guilt and innocence and that W cumulates the probabilities of votes for innocence from 0 through i votes. The expression for p is simply the proportion of votes for guilt that are attributable to guilty defendants, whereas P cumulates the proportion of votes attributable to guilty defendants from 0 through i votes.

Gelfand and Solomon (1973) demonstrated that the probability of a verdict is independent of T and that the correctness of a verdict is independent of jury size but does depend on the size of the quorum required for conviction. (This seeming contradiction of Walbert's analysis arises from the differences in the ways that the two models specify *correctness*.)

Using Poisson's (1837) data on French civil and criminal trials of the period from 1825 through 1833, Gelfand and Solomon (1973) obtained estimates of T and M by determining the probability of conviction in criminal cases at times when the required quorum for jury verdicts was either 7 of 12 votes (i.e., $W_{12,5}$ for the years 1825–1830) or 8 of 12 votes ($W_{12,4}$ for the years 1831–1833). With the knowledge that

$Y_{12,5} = W_{12,5} - W_{12,4}$, it was possible for Gelfand and Solomon to estimate the following overall parameter values: $T = .7494$, $M = .6391$, $P_{12,5} = .9406$, and $p_{12,5} = .9943$.

In their second article, Gelfand and Solomon (1974) applied similar methods to Kalven and Zeisel's (1966) data on first ballots and final verdicts in the 225 criminal cases cited by Walbert (1971). (See Table 1 for complete data.) In this instance their estimates of T and M were based on the overall distribution of verdicts reported in Table 1 and the various estimates this distribution provides for different Ys. Thus, 43 of the 225 (19%) juries produced first ballot, unanimous votes for guilt, so that one reasonable estimate of $Y_{12,0}$ is .19. Similar estimates of other Ys produce the following simultaneous equations:

$$Y_{12,0} = .19;$$

$$\sum_{i=1}^{5} Y_{12,i} = .47;$$

$$Y_{12,6} = .04;$$

$$\sum_{i=7}^{11} Y_{12,i} = .18;$$

$$Y_{12,12} = .12.$$

In their 1974 article, Gelfand and Solomon used the method of moments approach to find solutions for T and M, whereas in their 1975 article they treated the first ballot results as independent observations from a five-cell multinomial distribution and employed minimum chi-square and maximum likelihood estimation procedures to determine values for T and M. In each instance they also evaluated a three-parameter model in which M_1 is the probability that a juror will vote for guilt given a guilty defendant, M_2 is the probability that a juror will vote for innocence given an innocent defendant, and T is defined as before. The results of the three estimation procedures were roughly similar. The values of M_1 and M_2 clustered around .9 and did not appear to be significantly different (jurors appeared to be equally accurate in detecting guilt and innocence), while the values of T clustered around .7.

As noted earlier, the Gelfand and Solomon model is analogous to Walbert's binomial model, but uses two parameters rather than one. Gelfand and Solomon's model also allows a very simple comparison of the probability of conviction by 6- and 12-member juries for various values of T and M. Assuming majority persuasion and an equal split for guilt and innocence in juries who are initially evenly divided (precisely the assumptions made by Walbert), Gelfand and Solomon set the probability of conviction by a 12-member jury as

$$t = \sum_{i=0}^{5} Y_{12,i} + \tfrac{1}{2} Y_{12,6}$$

and the probability of conviction by a six member jury as

$$s = \sum_{i=0}^{2} Y_{6,i} + \tfrac{1}{2} Y_{6,3}.$$

Table 2 compares the values of t and s for $T = .2, .4, .6,$ and $.8$ and $M = .2, .4, .6,$ and $.8$.

Gelfand and Solomon (1974) took the position (one they retreated from in later articles)

Table 2
Probability of Conviction by 12-Man Jury, tw(T, M), *and 6-Man Jury,* s(T, M), *for Values of* T *and* M

T	$tw(T, M)$	$s(T, M)$
	$M = .2$	
.2	.793	.765
.4	.598	.588

	$M = .8$	
.2	.207	.235
.4	.402	.412
.6	.598	.588
.8	.793	.765

Note. Based on Gelfand and Solomon (1974).

that the differences in performance between 6- and 12-member juries are negligible over the full range of values for T and M. In fact, it is clear from Table 2 that whenever jurors vote correctly more than half the time, 12-member juries perform better than 6-member juries (i.e., they vote correctly more often). This is, of course, the same conclusion reached by Walbert (1971). Indeed, when one considers that there are thousands of criminal trials each year, it is also obvious that the otherwise negligible differences in performance may yield quite significant practical consequences, affecting thousands of lives.

Of course, we noted earlier that the Walbert model is less than ideal insofar as it fails to account for reversals of initial majorities and hung juries. In an effort to incorporate these two violations of the simple majority persuasion model, Gelfand and Solomon (1975) proposed that the Kalven and Zeisel data can provide the basis for more refined estimates of M, T, p, and P. Table 1 shows that all the cases with initial unanimous (12 to 0) votes for guilt ultimately returned guilty verdicts, 86% of the cases with between 7 and 11 votes for guilt did so, and half the cases with evenly divided juries did so, whereas 2% of the cases with initial though nonunanimous majorities favoring acquittal were reversed, the minority ultimately prevailing. On the basis of these results Gelfand and Solomon suggested the following equation for the probability that a jury will convict:

$$P_c = Y_{12,0} + .86 \sum_{j=1}^{5} Y_{12,j} + .50 Y_{12,6} + .02 \sum_{j=7}^{11} Y_{12,j}, \quad (7)$$

where, for example, $Y_{12,0}$ is the proportion of juries who begin deliberation with no votes for acquittal. Similarly, they suggested the following equation for the probability of acquittal:

$$P_a = Y_{12,12} + .91 \sum_{j=7}^{11} Y_{12,j} + .50 Y_{12,6} + .05 \sum_{j=1}^{5} Y_{12,j}. \quad (8)$$

The probability of a hung jury is thus $P_h = 1 - P_a - P_c$. Of course, not all acquittals and convictions are correct, but it is possible to determine the probability or proportion of convictions and acquittals that are correct. Thus,

$$P_{g/c} = (p_{12,0}Y_{12,0} + .86 \sum_{j=1}^{5} p_{12,j}Y_{12,j} + .50 p_{12,6}Y_{12,6} + .02 \sum_{j=7}^{11} p_{12,j}Y_{12,j})/P_c;$$

$$P_{i/a} = [P_a - (p_{12,12}Y_{12,12} + .91 \sum_{j=7}^{11} p_{12,j}Y_{12,j} + .50 p_{12,6}Y_{12,6} + .05 \sum_{j=1}^{5} p_{12,j}Y_{12,j})]/P_a.$$

Table 3 compares the results of the three methods of estimating the probabilities of interest for 12-member juries using Walbert's simple majority persuasion model and the more refined equations (7 and 8) proposed by Gelfand and Solomon.

To assess the reasonableness of the refined model, Gelfand and Solomon (1975) computed the values of P_c, P_a, P_h, $P_{g/c}$, and $P_{i/a}$ for different values of M and T and compared the results with the distribution of verdicts from the 225 Kalven and Zeisel cases cited earlier and with the overall distribution of verdicts from the 3,576 trials used in the entire Kalven and Zeisel (1966) study. Again, the best fits were produced with $M = .9$ and $T = .7$.

Finally, as noted above, Gelfand and Solomon (1975, 1977) used their maximum likelihood estimates of M and T in combination with Davis's (1973) social-decision-scheme analysis and by slightly modifying Davis et al.'s (1975) Scheme 3 produced a very good fit to the Kalven and Zeisel data: $P_c = .637$, $P_a = .303$, $P_h = .060$, $P_{g/c} = .9779$, and $P_{i/a} = .9385$—results that compare quite favorably with the results reported in Table 3.

Juror Accuracy and Satisfaction

Grofman (1976, in press) has employed a general binomial model similar to Gelfand and Solomon's for two purposes: to examine the effect of applying several simplifying assumptions to his model and to examine the implica-

Table 3
Comparison of Walbert's (1971) and Gelfand and Solomon's (1975) Jury Decision Models for 12-Member Juries

Study	Probability of outcome: Conviction	Acquittal	Hung	Defendant guilty given that jury convicts	Defendant innocent given that jury acquits
	Minimum χ^2 estimate

Gelfand & Solomon (1975)	.6340	.3059	.0601	.9930	.9175

tions for decision rule preferences of jurors' tolerance for verdict errors. We examine these analyses briefly, starting with the analysis of the simplifying assumptions.

Juror Acuity Model

Following Gelfand and Solomon (1973), Grofman (1976) associated a binomial p with the probability that a randomly selected juror will correctly judge innocent defendants to be innocent (P_{II}) and guilty defendants to be guilty (P_{GG}), where P_G is the proportion of defendants who are guilty, P_I is the proportion of defendants who are innocent (by definition, $P_I = 1 - P_G$), P_C is the proportion of defendants convicted by juries, P_A is the proportion of defendants acquitted by juries, P_H is the proportion of defendants whose juries hang, and q is the number of votes required for a verdict (either guilt or innocence) and corresponds to a de facto decision rule (when q votes are not obtained, the jury is assumed to hang). In developing his model, Grofman assumed for simplicity that $P_{II} = P_{GG} = p$ (i.e., that jurors are equally good at correctly determining guilt or innocence).

In some respects Grofman's model is a more general version of the Gelfand and Solomon (1973, 1974, 1975, 1977) model; Grofman's p and P_G correspond to Gelfand and Solomon's T and M.

As the first step in the construction of his model, Grofman examined the probability that a majority of jurors ($q = m$) in a jury with an odd number of jurors (N) will reach a correct verdict:

$$P\text{ (correct verdict)} = \sum_{h=m}^{N} \binom{N}{h} p^h (1-p)^{N-h}. \quad (9)$$

This expression is simply Equation 1 rewritten with $Q = m$ and with p as the probability that a juror will vote correctly. The general implications of this model are that when $p > \frac{1}{2}$, increasing the size of the jury also increases the probability that a majority will reach a correct verdict (while lowering the probability that a verdict will be reached); when $p = \frac{1}{2}$, the probability that a jury will reach a correct verdict is $\frac{1}{2}$ and is independent of jury size; and when $p < \frac{1}{2}$, the larger the size of the jury, the less likely it is to reach a correct verdict.

Equation 9 can also be used to create expressions for P_C, P_A, and P_{II}:

$$P_C = \sum_{h=q}^{N} \left[\binom{N}{h} p^h (1-p)^{N-h} P_G + p^{N-h}(1-p)^h P_I \right], \quad (10)$$

$$P_A = \sum_{h=q}^{N}\left[\binom{N}{h}p^h(1-p)^{N-h}P_I + p^{N-h}(1-p)^h P_G\right], \quad (11)$$

$$P_H = \sum_{h=N-q+1}^{q-1}\left[\binom{N}{h}p^h(1-p)^{N-h}\right]. \quad (12)$$

Equation 12 is a corrected form of Grofman's expression. Note that the first terms of Equations 10 and 11 determine the probability that q or more jurors will correctly vote for guilt or innocence, whereas the second terms determine the probability that q or more jurors will incorrectly vote for guilt or innocence (cf. Equations 5 and 6 in Gelfand & Solomon's, 1973, model). The P_H equation determines the probability that less than q jurors will concur on either guilt or innocence (note that when the decision rule is that the majority wins, P_H is the probability of an even split in juries with an even number of jurors, and $P_H = .0$ with odd-numbered juries). Note that P_H is independent of P_G and P_I.

Table 4
Distribution of First Ballot Votes When the Probability of a Juror Not Erring Equals .88 and the Probability the Defendant Is Guilty Equals .69

No. of votes	Total probability	Correct part	Incorrect part
Votes to convict			
12	.1488	.1488	.0
11	.2435	.2435	.0
10	.1826	.1826	.0
9	.0830	.0830	.0
8	.0255	.0255	.0
7	.0056	.0055	.0001
Votes to hang			
6	.0013	.0009	.0004
Votes to acquit			
7	.0026	.0025	.0001
8	.0115	.0115	.0
9	.0373	.0373	.0
10	.0820	.0820	.0
11	.1094	.1094	.0
12	.0669	.0669	.0

Note. Adapted from Gelfand and Solomon (1975).

Table 4 (based on Gelfand & Solomon, 1975) displays the probabilities of vote distributions from (0, 12) through (12, 0) that obtain from $p = .88$ and $P_G = .69$ and provides some insight into the operation of Equations 10–12. Note that the table is based on a 12-person jury using a majority decision rule. If the decision rule were 8 of 12 votes, the hung portion of the table would consist of the sum of the probabilities of the (7, 5), (6, 6), and (5, 7) distributions.

Grofman (1976) observed that if jurors are very accurate in assessing guilt and innocence, then the values for P_A and p_C are approximated by the first terms of Equations 10 and 11. From Table 4 it is clear that for a 12-member jury with $p = .88$ and a majority decision rule, Grofman's observation is quite correct—deleting the "incorrect" portions of the P_A and P_C terms loses only .02% of the cases.

If one further assumes that the decision rule is unanimity, then the equations simplify even further:

$$P_C \approx p^N P_G, \quad (13)$$

$$P_A \approx p^N P_I, \quad (14)$$

$$P_H \approx 1 - p^N, \quad (15)$$

where

$$P_G \approx \frac{P_C}{P_C + P_A},$$

$$P_I \approx \frac{P_A}{P_C + P_A},$$

$$p \approx (P_C + P_A)^{(1/n)}.$$

Grofman correctly observed that with the appropriate normative data, it is relatively easy to estimate the parameters P_G, P_A, and p, but in making his estimates he assumed that the appropriate data are the distribution of final jury verdicts when, in fact, the appropriate data are the distribution of initial ballots. Grofman assumed that he could treat q as though it were an effective decision rule (similar to the analyses of Davis, 1973, and Walbert, 1971); however, the simplifying assumptions that led him from Equations 10, 11, and 12 to Equations 13, 14, and 15 used restrictions on q that effectively changed the decision rule from a majority decision to unanimity rule. As Saks and Ostrom (1975) demonstrated, the effect of such restrictions is

to lower the probability that a jury will produce a verdict on the first ballot. (As can be seen from Table 4, when $p = .88$ and $p_G = .69$, only slightly more than one fifth of the juries can be expected to produce a verdict on the first ballot with a decision rule of unanimity.)

It is, therefore, appropriate to estimate the parameters of the simplified model using data on first ballot distributions. The estimates obtained using the Kalven and Zeisel (1966) data are $P_G = .6232$, $P_I = .3768$, $p = .9062$, and $P_H = .6933$. That the estimates are roughly equivalent to those made by Gelfand and Solomon (1975) should not surprise one, since Grofman's simplifying assumptions allow a straightforward estimation of the same parameters. The estimates are cruder because the simplified equations are based on initial vote distributions at the tails of the binomial distribution—(12, 0) and (0, 12)—but the similarity of the estimates produced by the two procedures tends to confirm the validity of Grofman's simplifying assumptions.

One might take this analysis one step further and use the data on final verdicts to assess first ballot parameter values. If, for instance, one regards final verdicts as the best available index of defendants' convictability or "acquittability," then the Kalven and Zeisel (1966) data in Table 1 indicate that 139 (61.78%) of the 225 defendants were convictable, that 73 (32.44%) were acquittable, and that in 13 cases (5.7%) the guilt or innocence of the defendant was ambiguous. One can now ask, what is the probability that a convictable (acquittable) defendant will be convicted (acquitted) on the first ballot? The answer is that 43 of the 139 defendants ultimately convicted were convicted on the first ballot (30.94%), whereas 26 of the 73 defendants ultimately acquitted were acquitted on the first ballot (35.62%).

Thus, the probability that an individual juror will vote to convict a convictable defendant on the first ballot is $.3094^{1/12}$ or .9069, and the probability that an individual juror will vote to acquit an acquittable defendant on the first ballot is $.3562^{1/12}$ or .9176. These results are in close agreement with the Gelfand and Solomon and Grofman estimates and suggest that jurors may be somewhat more reluctant to vote to convict an apparently guilty defendant on the first ballot than they are to vote to acquit an apparently innocent defendant. As before, of course, this analysis tells one nothing about the deliberation process itself; it merely provides a crude method for assessing first ballot, individual juror accuracy.

Juror Tolerance for Errors

Following the analyses of Rae (1969), Taylor (1969), Curtis (1972), and Badger (1972), Grofman (1976) has used his basic binomial model (Equations 8, 9, and 10) to explore the decision rule implications of various levels of juror tolerance for erroneous jury decisions. He first specified a trade-off ratio R that reflects the number of guilty defendants a juror would be willing to set free to avoid the erroneous conviction of one innocent defendant. Two ratios can be constructed using R: $P_R = R/(R+1)$ is the relative weight attached to avoiding false convictions (avoiding a Type I error) that Grofman analyzes as the weight attached to assuring correct convictions and $1 - P_R = R/(R+1)$ is the relative weight attached to assuring correct convictions of guilty defendants (avoiding a Type II error) that Grofman analyzes as the relative weight attached to avoiding false convictions. By way of example, if a juror is willing to set five guilty defendants free to avoid one false conviction, then $P_R = 5(5+1) = 5/6$ and $1 - P_R = 1/6$. (For discussions of Type I and Type II errors in legal contexts, see also Feinberg, 1971; Friedman, 1972; Tribe, 1971.)

By weighting the probability of correct voting to reflect the trade-off ratio P_R for Type I and Type II errors, a new equation can be formed for the weighted probability that a quorum q will produce a correct verdict:

$$\sum_{h=0}^{q-1}\left[\binom{N}{h}p^{N-h}(1-p)^h P_I P_R\right] + \sum_{h=q}^{N}\left[\binom{N}{h}p^h(1-p)^{N-h}P_G(1-P_R)\right]. \tag{16}$$

The second term of Equation 16 corresponds to the first term of Equation 10 and is simply the weighted probability that q or more jurors will correctly vote for conviction. The first

term of Equation 16 is related to the first term of Equation 11, but in addition to including all the cases in which q or more jurors correctly vote for acquittal, the first term of Equation 16 also includes the cases in which the jury hangs (from $h = 0$ through $q - 1$). In essence, Grofman's analysis treats hung juries as correct acquittals.

Although Grofman again regarded q as the effective decision rule, his analysis is appropriately treated as an analysis of first ballots rather than of final verdicts. This means, as we have noted before, that the analysis fails to account for those cases in which final verdicts are not characterized by majority persuasion (approximately 5% of the cases reported in Kalven & Zeisel, 1966). Given the limitations on one's knowledge about the deliberation process, Grofman's treatment of q as an effective decision rule is not fatal and has the advantage of simplifying his analysis. The question of interest, of course, concerns what decision rule will maximize the value of Equation 16.

For fixed ns, Grofman determined the values of q that maximize the expression for given levels of p, P_G, and P_R. Of greatest interest are those conditions in which juror accuracy is greater than one half (in which case q should be equal to or greater than a majority m). Grofman noted in particular that when $P_G > 1/2$, the optimal decision rule approaches or equals $q = n$ as P_R approaches 1. Grofman concluded "that it does not require an infinite value of R to justify in normative terms a decision rule requiring unanimity to convict!" (p. 11).

In a similar fashion, Grofman constructed an index of juror satisfaction (D) that reflects the subjective ratio of disappointment a juror experiences when an apparently innocent defendant is convicted compared with the disappointment experienced when an apparently guilty defendant is set free. (Disappointment is *subjective* insofar as a juror can rarely know with certainty that a defendant is objectively guilty or innocent and can only judge on the basis of trial evidence.) The relative disappointment of a Type I error can be denoted by $P_D = D/(D + 1)$ and a Type II error by $1 - P_D = D/(D + 1)$. Thus, if a juror is nine times more disappointed by an erroneous conviction than by an erroneous acquittal, $D = 9$, $P_D = 9/(9 + 1) = .9$, and $1 - P_D = .1$.

Using the trade-off ratio for disappointment, the weighted probability that a randomly selected juror will agree with a verdict (i.e., the juror's perception of the correctness of other jurors' assessments of the evidence) is expressed by

$$\sum_{h=q-1}^{N-1} \binom{N-1}{h} p^{h+1}(1-p)^{N-h-1} P_G P_D$$
$$+ \sum_{h=q-1}^{N-1} \binom{N-1}{h} p^{h+1}(1-p)^{N-h-1} P_I (1 - P_D). \tag{17}$$

(This expression includes a correction of a typographical error in Grofman, 1976.)

The first term of the expression is the weighted probability that a juror will join a quorum that will correctly convict, while the second term is the weighted probability that a juror will join a quorum that will correctly acquit. Grofman concluded from his analysis that the value of Expression 17 is maximized when the decision rule corresponds directly to the juror's trade-off ratio P_D (for a related analysis, see Curtis, 1972). Thus, if a juror is as disappointed by seeing two guilty defendants acquitted as by seeing one innocent defendant convicted ($P_D = \frac{2}{3}$), that juror should prefer a two-thirds decision rule. Again, of course, we caution that this analysis is most appropriate for first ballot distribution and would require modification if it were extended to final verdicts.

Both the Gelfand and Solomon and the Grofman analyses of prior probabilities of guilt and juror accuracy are based on data from a wide range of cases. In some of those cases the evidence of guilt was probably overwhelming, in some cases the evidence of guilt was probably fairly weak, and in many cases the evidence was probably relatively balanced. Because the estimates of the parameters used in the models are based on a range of cases, they may not be directly applicable to any particular case. In general, the results suggest that approximately 70% of the defendants brought to trial (in the cases examined by Kalven and Zeisel) are convictable and that jurors are on the

average about 90% accurate in their assessments of defendants' convictability. This does not mean that any particular defendant has a 70% chance of conviction, nor does it mean that one can expect 10% of the jurors to err in their judgments of a particular defendant's guilt. The Gelfand and Solomon and Grofman analyses simply are not appropriate for analysis of individual cases. Indeed, it is possible that the convictability and juror accuracy parameters (assumed to be independent in the two models) are in fact interrelated and that juror errors are most likely to occur in cases in which the evidence against and in favor of a defendant is relatively balanced. In cases in which the evidence points unequivocally in one direction or another, it is probably less likely that jurors will err. Existing data on juror behavior are not adequate to the task of determining the relationship between apparent guilt and jury acuity, but the reasonableness of the assumption of independence should be kept in mind when evaluating the parameter estimates provided by the models we have examined.

The aspect of both Gelfand and Solomon's and Grofman's analyses that we find most disturbing is the implication that there are only two distinct types of defendants: defendants who clearly should not be convicted on the weight of the trial evidence ($\approx$30% of all defendants) and for whom the probability that a juror will erroneously vote to convict is $\approx$.1 and defendants who clearly should be convicted on the weight of the trial evidence ($\approx$70% of all defendants) and for whom the probability that a juror will correctly vote to convict is $\approx$.9 (see sample results reported in Table 3).

Although such a view may provide a reasonable characterization of trial evidence and of jurors' assessment of that evidence, we think that this analysis obscures the fact that the evidence presented at trials probably varies widely in the extent to which it indicates a defendant's guilt or innocence. In some cases the evidence may overwhelmingly and unmistakably point to guilt or innocence, and with such evidence we would not be surprised to see unanimous first ballot verdicts. In other instances the evidence may be very close (some of it pointing to innocence and some pointing to guilt), and in these trials we would not be surprised to find the jury dividing equally for conviction and acquittal on the first ballot.

Basically, we think it misleading to conceive of juror accuracy in Gelfand and Solomon's terms—juror accuracy is, after all, limited by the quality of the evidence presented at trial. Optimal juror performance can probably be attained only under circumstances such as those outlined in the discussion of Saks and Ostrom's (1975) and Walbert's (1971) binomial models: With very large juries, defendants should only be convicted when a majority (or some other critical proportion) of the jurors vote to convict after hearing all the trial evidence. We think it more realistic to assume that the weight of trial evidence (the extent to which the evidence would convince a juror of the defendant's guilt) varies widely across trials and that the best indication of the variability in trial evidence weight is the variability in jurors' first ballot votes for conviction and acquittal.

Judging from Kalven and Zeisel's (1966) data on first ballot votes (Table 1), it appears that the weight of evidence is bimodally distributed and that in approximately 70% of the cases the evidence points to conviction. Because Table 1 provides only summary data on the distribution of votes (i.e., juries produce unanimous verdicts for conviction in 19% of the cases, produce nonunanimous majorities for acquittal in 18% of the cases, and produce unanimous verdicts for acquittal in 12% of the cases), one cannot fix the actual distribution of first ballot votes (or the underlying distribution of evidentiary weight that produces the first ballot distribution of votes). Still, one can test some possible distributions of evidentiary weight across trials (in which such weights represent the probability that a randomly selected juror who has heard the evidence from a particular trial will vote to convict) for their fit to the Kalven and Zeisel first ballot vote distribution.

For example, the Gelfand and Solomon (1975) model that produces the distribution of votes shown in Table 4 assumes a distribution of evidentiary weight in which the probability that a juror will vote to convict is .88 for 69% of the cases and .12 for 31% of the cases. This very simple bimodal distribution of evidence produces a moderately good fit to the Kalven

and Zeisel data. We have tested several other types of evidentiary weight distributions (relatively flat but skewed, unimodal, and bimodal) and have assumed in each instance that the weights are distributed in probability intervals of .1. We have found that bimodal distributions of evidence such as the one in Figure 2 produce the best fits to the Kalven and Zeisel data. (We caution that this estimation enterprise is crude; it is subject to the limitations of the data, it is post hoc, and it ignores that the distribution of evidence is probably continuous rather than discrete. Still, the distribution in Figure 2 is psychologically plausible and, as we demonstrate, produces a good fit to the distribution in Table 1.)

To explain our method briefly, one can see that the distribution of weights in Figure 2 implies that in 13% of all cases jurors are expected to judge the evidence against a defendant as unmistakably indicating that the defendant is guilty. In these cases the probability that jurors will vote to convict is equal to 1.0—Each of these juries will return unanimous verdicts for conviction (the expected outcome for a binomial $p = 1.0$ and for $N = 12$). In 8% of the cases Figure 2 implies that all jurors will vote for acquittal ($p = .00$). Similarly, in 16% of the cases the (binomial) probability that a randomly selected juror will vote to convict equals .8.

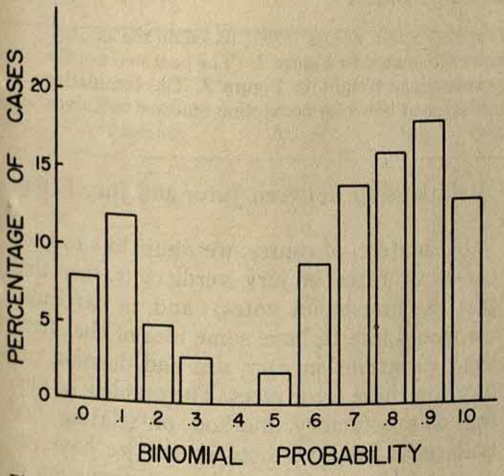

Figure 2. Hypothetical distribution, across cases, of evidentiary weight for conviction (based on data collected by Kalven & Zeisel, 1966).

By consulting binomial tables or using the binomial expansion for $N = 6$ and $N = 12$, one can determine the expected distribution of first ballot votes for the distribution of ps shown in Figure 2.

Figure 3 shows the expected distributions of votes for each of the binomial probabilities for 12-member juries. The figure also shows the cumulative probability of each vote distribution (i.e., if the evidence weight is distributed as shown in Figure 2, then in 12-member juries a unanimous verdict for acquittal should occur in 11.7% of the cases, with the bulk of these verdicts occurring in trials in which the evidence points unequivocally to innocence). The cumulative distribution of first ballot votes in the 12-member jury (shown at the top of Figure 3) provides a very good fit to the Kalven and Zeisel data (11.7%, 18.4%, 3.8%, 46.5%, and 19.4% in the model vs. 12%, 18%, 4%, 47%, and 19% in the respective categories for the normative data).

By making a few simple assumptions, one can also assess the distribution of first ballot votes for accuracy. For example, if one makes the crude assumption that juries should convict whenever the binomial probability of guilt is equal to or greater than .6 (i.e., when 60% or more of all jurors who might hear a case would vote to convict), should hang when $p = .5$, and should acquit when $p \leq .4$, then one can easily determine the number of juries that began deliberation with "errorful" first ballot distributions (e.g., in Figure 3 when $p \geq .6$, all the juries who have produced less than seven votes for conviction have made errors, since one has assumed that defendants with evidentiary weights of .6 or more should be convicted). In Figure 4 we display the proportions of cases in each category of initial votes, ranging from (0, 12) to (12, 0), that would convict, hang, and acquit if one applied the simple rules outlined above. Overall, the probability that a jury will begin deliberations with a majority erroneously preferring acquittal is 1.9% in 12-member juries, while the probability that a jury will begin deliberations with a majority erroneously preferring conviction is .1%. These values can be compared with the much lower error rates produced by Gelfand and Solomon's model (see Table 4). Although the absolute value of the estimates

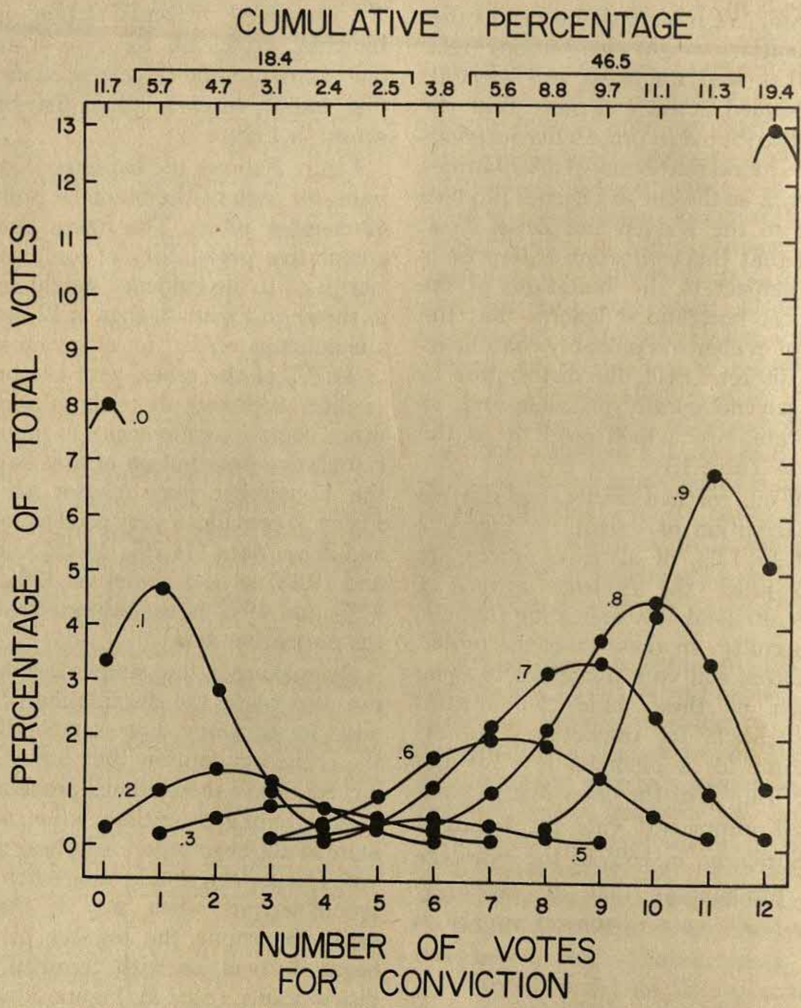

Figure 3. Distribution of first ballot vote percentages for conviction across juries, based on the assumption of a bimodal distribution of evidence such as the one illustrated in Figure 2. (The parameter of the plotted subdistributions in Figure 3 corresponds to evidentiary weight in Figure 2. The cumulative distribution totals, 18.4 and 46.5, correspond to the tabulation of votes for conviction reported in Kalven & Zeisel, 1966, and reproduced in Table 1.)

produced by the model we have developed in this section can be questioned (more complete data on the Kalven and Zeisel juries would heighten our confidence), we think that this model of juror accuracy is superior to Gelfand and Solomon's and Grofman's because it makes more plausible assumptions about the distribution of trial evidence weights. Since the distribution of first ballot votes produced by the model fits the normative data better than Gelfand and Solomon's model, we are also confident that Gelfand and Solomon's model underpredicts first ballot error rates.

Relationship Between Juror and Jury Errors

Ultimately, of course, we would like to know the error rates in jury verdicts (rather than just the first ballot votes); and, in particular, we would like to have some idea of the effects that variations in jury size and decision rule have on these error rates. The problem of finding a satisfactory method of relating first ballots to final verdicts is one we have encountered several times in our discussion of various mathematical models. Although we have criticized all of the proffered solutions to

this problem, we think that a decision scheme approach such as Davis's (1973) offers the most promise. Simply for purposes of illustration, we have applied the decision schemes in Table 5 to the initial vote distributions in Figure 2 to acquire a sense of the impact that different decision rules (unanimous vs. two thirds) might have on jury accuracy.

The decision schemes in Table 5 are based largely on the results of a computer simulation of jury decision making that is discussed later in this article (see also Penrod & Hastie, Note 6). These decision schemes are constructed to produce a slight postdeliberation bias toward acquittal, such as is observed in the Kalven and Zeisel (1966) data (in Table 1, more majorities reverse in the direction of acquittal than in the direction of conviction). These decision schemes are also roughly comparable with Gelfand and Solomon's (1975, 1977) version of Davis et al.'s (1975) Scheme 3.

Before discussing the results of this decision scheme analysis, it should be noted that these decision schemes reflect relatively unfavorable views of the deliberation process insofar as they assume that both correct and errorful initial majorities are equally likely to be reversed during deliberation. In other words, these decision schemes do not assume that deliberation serves to correct the errors made in first ballot votes. If deliberations did serve a correcting function, then one would expect the probability of a reversal in a first-ballot-error case to be higher than the probability of a reversal in an initially correct case. As one will see, our analysis indicates that the selection of optimal jury sizes and optimal decision rules

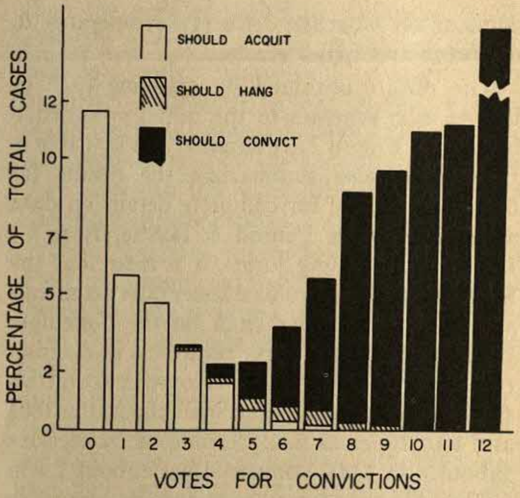

Figure 4. Distribution of percentage of votes for conviction across cases generated by the assumptions of the analysis outlined in Figures 2 and 3 and in the text. (Solid areas represent juries under conditions with evidentiary weights for conviction greater than .50, hatched areas represent juries with weights equal to .50, and clear areas represent juries with weights less than .50.)

Table 5
Decision Schemes

Votes for conviction	p of verdict in unanimity (12/12) rule			p of verdict in 8/12 rule		
	Acquit	Hang	Convict	Acquit	Hang	Convict
0	1.0			1.0		
1	1.0			1.0		
2	1.0			1.0		
3	1.0			1.0		
4	.92	.07	.01	1.0		
5	.70	.26	.04	.70	.26	.04
6	.35	.40	.25	.35	.40	.25
7	.14	.26	.60	.14	.26	.60
8	.04	.07	.89			1.0
9			1.0			1.0
10			1.0			1.0
11			1.0			1.0
12			1.0			1.0

Note. In 12/12 and 8/12 rule, the denominator indicates jury size and the numerator denotes the number of votes needed for a decision.

depends on whether deliberation operates to minimize first ballot errors.

The results obtained by applying each of the decision schemes to the initial vote distributions in Figure 2 are summarized in Table 6. (The table also summarizes the results for 6-member juries; for complete details on data and methods see Penrod & Hastie, Note 6.) If one ignores hung juries, it is clear that the 12-member juries produce fewer false acquittals and false convictions than do the 6-member juries: The smaller jury, regardless of decision rule, produces 50% more erroneous acquittals (about 5 in 100 compared with about 3 in 100) and four times as many erroneous convictions (about 6 in 1,000 compared with about 1.4 in 1,000). These same relationships are also evident in the probabilities that a defendant is guilty if convicted ($P_{G/C}$), innocent if convicted ($P_{I/C}$), innocent if acquitted ($P_{I/A}$), and guilty if acquitted ($P_{G/Z}$). (These probabilities can be compared with the 12-member probabilities produced by Gelfand & Solomon's model; see Table 3.)

Somewhat surprisingly, the error rates in nonunanimous juries are lower than the rates in the corresponding unanimous juries. The reason for this is that the decision schemes used to generate the final distributions of verdicts do not use the corrective factor discussed earlier. This point can be illustrated by examining the distribution of error cases in 12-member juries who produce eight votes for conviction on the first ballot. One can see in Figure 4 that most such juries' votes are consistent with the evidence, but a few "should" have begun deliberation with even splits. If these juries use a unanimous decision rule, one can see from Table 5 that 4% of the juries can be expected to reverse the original majority and produce verdicts for acquittals. Since the decision scheme does not distinguish between error cases and correct cases, the result is that 4% of the cases that start with errors will be corrected, while 4% of the cases that begin deliberation with majorities correctly preferring conviction will erroneously acquit. In essence, the decision scheme ultimately creates more errors than it corrects. For juries using an 8/12 decision rule, this problem is avoided—none of the original error

Table 6
Decision-Scheme-Generated Verdicts and Verdict Accuracy for 6- and 12-Member Juries Assigned Unanimous and Nonunanimous Decision Rules for N = 100 Cases

Jury decision	Acquittal			Hung case			Conviction			Total			Condition[a]			
rule[a]	COR	SHH	SHC	COR	SHC	SHA	COR	SHH	SHA	Convicted	Hung	Acquitted	$P_{G/C}$	$P_{I/C}$	$P_{I/A}$	$P_{G/A}$

Note. COR = correct, SHH = should have hung, SHC = should have convicted, and SHA = should have acquitted. $P_{G/C}$ = the probability that a defendant is guilty given that the defendant is convicted. $P_{I/C}$ = the probability that a defendant is innocent given that the defendant is convicted. $P_{I/A}$ = the probability that a defendant is innocent given that the defendant is acquitted. $P_{G/A}$ = the probability that a defendant is guilty given that the defendant is acquitted.
[a] The denominator of the decision rule indicates jury size, and the numerator indicates the number of votes needed for a decision.

cases are corrected, but no new error cases are created.

Although we have only limited confidence in the absolute value of the entries in Table 6 (since neither the initial distribution of evidence nor the decision schemes are well-grounded empirically), these results suggest that one's ability to distinguish among optimal decision rules may ultimately depend on one's ability to specify the extent to which jury deliberations serve to correct the "sampling errors" in the distribution of initial votes. Our guess is that a unanimous decision ultimately operates to minimize jury errors: First, it minimizes the probability of an incorrect verdict on the first ballot, and second, it maximizes the opportunities for jurors who have correctly assessed the weight of the evidence to communicate the grounds for their assessments to other jurors, who may then be persuaded to adopt a more accurate view of the evidence. Stated another way, we contend that it is unlikely that reversals of majorities are equally likely for initially correct and incorrect juries. Given the small magnitude of the advantages enjoyed by the non-unanimous juries under the equally likely decision schemes we have used (Table 6 shows that the advantages in the critical false-acquittal and false-conviction categories are very small), it is clear that even a relatively small correcting factor in jury deliberations would give the edge to the unanimous decision rules. As a practical matter, our results indicate that it is important to direct future research to the question of whether deliberation serves to minimize verdict errors. If there is something about the deliberation process that does serve to raise the probability that initial errors will be corrected, then the unanimous decision rule is probably preferable.

To conclude the section on models of juror accuracy we examine a model developed by Nagel and Neef (1975). Nagel and Neef have also tackled the question of the relationship among jury size, decision rules, and error rates, using an approach that is similar to but less general than Grofman's (1976) approach. Perhaps the most important difference between the two lines of analysis is that Nagel and Neef were concerned with defendants' objective or true guilt and innocence rather than the guilt or innocence indicated by the evidence presented at trial (what Gelfand and Solomon called "convictability"). A second important difference is that Nagel and Neef made specific assumptions about the values of the parameters they used in their model and then examined the results obtained with these specific parameter values.

Their analysis proceeded in two stages: First, they analyzed *individual* juror behavior (what we regard as *first ballot* behavior), and then they examined individual plus *collective* behavior (what we would consider to be an analysis of jury verdicts). Nagel and Neef's analysis can most clearly be understood by noting the assumptions about objective guilt and innocence and juror accuracy on which their analysis is based. First, they assumed that the number of truly guilty defendants brought to trial is relatively large (95%), while the number of truly innocent defendants is relatively small (5%). Although we consider the grounds for this assumption rather curious (it is based on an analogy to the .05 significance level used in statistical analysis), we do not quarrel with the reasonableness of the assumption; indeed, we have heard experienced defense attorneys make even lower estimates of the error rate in indictments. (Of course, since only about 10% of all criminal indictments reach trial—most defendants plea bargain—it is possible that truly innocent defendants are overrepresented at the trial stage.) The basic implication of Nagel and Neef's assumption is that it is relatively uncommon to find instances in which evidence sufficient for indictment points to the wrong defendant and that prosecutors are reasonably accurate in their indictments.

Next, Nagel and Neef assumed that 40% of all truly innocent defendants are erroneously convicted by juries (i.e., 2 in 100 cases yield false convictions), compared with a 70% conviction rate for truly guilty defendants (they made this estimate by reference to the Kalven & Zeisel, 1966, data that are presented in Table 1). Disregarding deliberation effects (a point to which we return), Nagel and Neef used the 40% and 70% figures to posit that the probability that an individual juror will erroneously vote to convict a truly innocent defendant is $.4^{1/12}$ or .926, whereas the proba-

bility that an individual juror will correctly vote to convict a truly guilty defendant is $.7^{1/12}$ or .971. Finally, Nagel and Neef assumed they could use these individual probabilities in the binomial expansion to determine the weighted probabilities of false convictions and false acquittals for various jury sizes and decision rules (fundamentally the method used in Grofman's, 1976, analysis). For ease of presentation, Nagel and Neef reported their results in terms of 1,000 cases in which 95% (950) of the defendants were truly guilty and 5% (50) were truly innocent. The results of their analysis (in which false convictions were given a weight of 10 compared with a weight of 1 for false acquittals) indicate that with binomial probabilities of .926 and .971, seven-member unanimous juries produce the minimum weighted sum of errors and 11/12 and 10/12 juries produce the lowest weighted sum of errors for nonunanimous juries of various sizes.

Unfortunately, we regard this analysis as faulty at several points. First, by taking the 12th root of the .4 and .7 probabilities, Nagel and Neef implicitly adopted the 12-member unanimous jury as the absolute standard against which all other jury sizes and decision rules are to be evaluated. Nagel and Neef failed to justify using $p^{1/12}$ as a standard individual probability. Second, because they used these probabilities in the binomial expansion to determine the probability that X or more jurors (where X is the decision rule quorum) in a jury with Y members will vote to convict in Y binomial trials, their initial analysis produced the curious result that all juries failing to attain the required quorum in Y binomial trials were treated as acquittals, even though they may have been only one vote short of the necessary quorum for conviction. As one saw before (e.g., in Walbert's, 1971, analysis), for any fixed binomial probability, any reduction in the number of binomial trials (i.e., any reduction in the number of jurors who constitute a jury) increases the probability that all the jurors (or some set proportion of the jurors) will agree on an outcome. Given this fact, the real problem with Nagel and Neef's analysis is that they failed (as did some of the other mathematical modelers we have considered) to make an adequate distinction between individual juror accuracy (first ballots) and jury accuracy (verdicts).

It is appropriate to say that Nagel and Neef's initial analysis assessed weighted errors in the first ballot verdicts produced by juries of varying size who used various decision rules. Their analysis is comparable with the binomial analysis in Figure 1 and Gelfand and Solomon's (1973, 1974, 1975) analysis. What Nagel and Neef's method potentially adds to these other analyses is the emphasis on weighting errors in first ballot verdicts. With respect to these weights, we note that changes in the relative weights attached to false acquittals and convictions will affect the optimal jury size and decision rules. (For example, if false convictions are given a weight of 14 rather than 10, the advantage in weighted errors on first ballot verdicts shifts to the 12-member jury.)

Although Nagel and Neef failed to mention several of the shortcomings in their model, they were aware that the model does a poor job of accounting for the effects of group deliberation on the accuracy (and even the distribution) of jury verdicts. They attempted to overcome this difficulty by arguing that the final verdict distribution is a product of both individual (or *independent*) factors and collective factors. Thus, that 64% of the defendants in the Kalven and Zeisel trials (see Table 1) were convicted by unanimous juries is taken as an index of the collective factors, whereas $.64^{1/12}$ is taken as an index of the independent factors. The collective factors plus the independent factors are presumed to be reflected in the fact that after deliberation 67.7% of the jurors in the 225 Kalven and Zeisel trials voted to convict (when jurors in hung juries are taken into consideration). This 3.7% difference (67.7% − 64%) is, according to Nagel and Neef, attributable to a weighted combination of individual and collective factors:

$$.677 = \left[\frac{W(.64)^{1/n} + .64}{W + 1}\right],$$

where $W = .13$ and $n = 12$. Nagel and Neef's analysis assumed that this relative weighting of independent and collective factors (11% independent and 89% collective) prevails across all decision rules and jury sizes.

We are troubled by this conception of the deliberation process and the calculations to

Table 7
Jury Verdict Errors for Objectively Innocent and Objectively Guilty Defendants

Jury decision rule[a]	% of total no. convictions		% of total no. acquittals		Unweighted sum of errors	Weighted sum of errors[b]
	Correct	Incorrect	Correct	Incorrect		
12/12	60.60	3.19	1.583	30.07	320.6	619.7
8/12	61.71	3.25	1.577	29.95	332.0	624.5
6/6	59.26	3.12	1.647	31.29	344.1	624.9
4/6	60.64	3.19	1.644	31.24	344.3	631.4

[a] The denominator of the decision rule indicates jury size, and the numerator indicates the number of votes needed for a decision.
[b] The weight ratio was 10:1.

which it gives rise. First, it is not clear what this "combined" model really captures. The relative weight of the independent factor is determined solely by the relative imbalance of juror votes in hung juries (13 of the 225 juries in the Kalven and Zeisel trials) averaged over all 225 juries. (Actually, it is not clear that Nagel & Neef's analysis was based on the distribution of votes in the 13 hung cases reported in Table 1; although they implied that they used these 13 cases, their footnotes indicate they may have drawn on a different sample of 48 hung juries.) Irrespective of their data source, it is clear that Nagel and Neef's analysis depends on the level of disagreement in hung juries—if there were no hung juries (or if in all hung juries the proportion of jurors favoring guilt were the same as the proportion of juries who convicted), there would be no independent factor; the combined probability would be identical to the collective probability, and W would equal zero. What Nagel and Neef have done is to take a small bias (toward conviction) in the distribution of votes in a very small number of cases and argue that this bias reflects the individual juror's imperviousness to group influence. Furthermore, by assuming that this independence factor accounts for 11% of the decision making in all jury sizes and decision rules, they have ruled out the possibility that differing jury sizes and decision rules operate directly to affect the extent of group influence on individual jurors (and thereby to affect the distribution of verdict errors). In fact, the evidence that jury size can affect hanging rates (e.g., Kalven & Zeisel, 1966; Padawer-Singer & Barton, Note 1) suggests that the relative impact of independent factors varies with jury size. (Though it is perhaps a less telling defect, Nagel and Neef did not include the possibility of hung juries being produced by their model.)

In addition to the conceptual problems of the combined model, Nagel and Neef's analysis of verdicts is also based on a binomial model in which the probability of a conviction equals the probability that a quorum will be obtained in Y binomial trials. The verdicts of nonquorum juries are once again treated as acquittals, even though the juries may fall only one vote short of a quorum (many such cases end up being added to the error cases for false acquittals).

Although we have chosen not to report the results of Nagel and Neef's verdict analysis (for the reasons enumerated above), we do applaud their efforts and think that with a better formulated verdict model, it would be worthwhile to pursue and test their assumptions about objective guilt and innocence and the effects that different jury sizes and decision rules have on error rates.

One possible approach might make use of the model, developed earlier in this section, that assumes the weight of trial evidence is bimodally distributed. In Figure 2 we used the binomial expansion to generate a distribution of first ballot votes and then applied the decision schemes shown in Table 5 to assess the error rates in final verdicts. If, in common with Nagel and Neef, we are interested in testing inferences about the effects of jury size and decision rule on the weighted probability of false convictions of truly guilty defendants and false acquittals of truly guilty defendants, we can use the same model and, by making

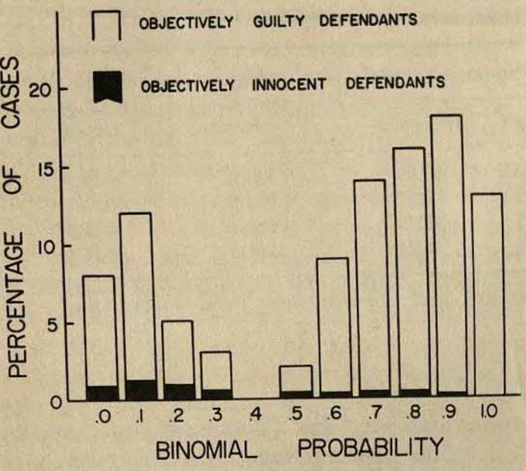

Figure 5. Hypothetical distribution across cases of evidentiary weight for conviction, incorporating the Nagel and Neef (1975) assumption that the distribution of weights is dependent on objective guilt or innocence of the defendant.

reasonable assumptions about the distribution of evidentiary weight against objectively guilty and innocent defendants, assess the probabilities of conviction and acquittal errors for objectively guilty and innocent defendants.

For instance, if we assume (as did Nagel and Neef) that 5% of all defendants are truly innocent and make the further assumption that the evidence against truly guilty and innocent defendants is identically distributed, we can examine the overall distribution of verdicts in Table 6 to assess error rates for different jury sizes and decision rules. As the results in Table 7 demonstrate, with a weight ratio of 10:1, the 12 unanimous juries produced the lowest weighted sum of errors.

A somewhat more complex analysis might incorporate Nagel and Neef's assumption that truly innocent defendants are less likely to be convicted than truly guilty defendants (.4 vs. .7). This assumption can be incorporated into the model by assuming that the evidence against truly innocent defendants is not distributed identically to the evidence against truly guilty defendants, but is skewed in the direction of acquittal. A distribution of evidence such as the one in Figure 5 captures this notion. This distribution of evidence could be used to generate a distribution of verdicts that could then be subjected to an analysis for errors (including an analysis of the weighted sum of errors).

An analysis such as the one advanced here has the advantage of testing the effects of jury size and decision rule variations on error rates (given a variety of assumptions about the distribution of the weight of evidence against objectively guilty and innocent defendants) in the context of a model that straightforwardly relates jury verdicts to initial votes by individual jurors.

Summary Comments on Mathematical Models

As we have noted above, one of the major shortcomings of the mathematical models of jury decision making is the weakness of their assumptions about the relationship between first ballots and final ballots. As one has seen, Saks and Ostrom (1975) did not confront the problem. Walbert (1971) made the simple assumption that verdicts are governed by majority persuasion, with initially evenly divided juries splitting equally for conviction and acquittal, but his model fails to account for reversals of initial majorities and juries that ultimately hang. Gelfand and Solomon (1973, 1974, 1975, 1977) gave little consideration to the relationship of first ballot distributions to final verdicts, for they were able to estimate their parameters simply by examining post hoc, aggregate relationships between first ballots and final verdicts without making assumptions about the intervening processes.

Grofman's (1976) and Nagel and Neef's (1975) models of juror accuracy also suffer from an inability to treat final verdicts, except under the simplest of assumptions about the relationship of first and final ballots.

Davis (1973) and Davis et al. (1975) addressed the problem of modeling social processes and employed a post hoc analysis of first ballots and final verdicts to find the implicit or effective decision rule that best fits the aggregate data. Although good aggregate fits are obtained, no one decision scheme has consistently provided the best fit. Furthermore, when nonaggregated analyses of initial ballots and final verdicts from individual juries have been made, the predictive accuracy of the best fitting models has proven unreliable (Davis, Kerr, Stasser, Meek, & Holt, 1977;

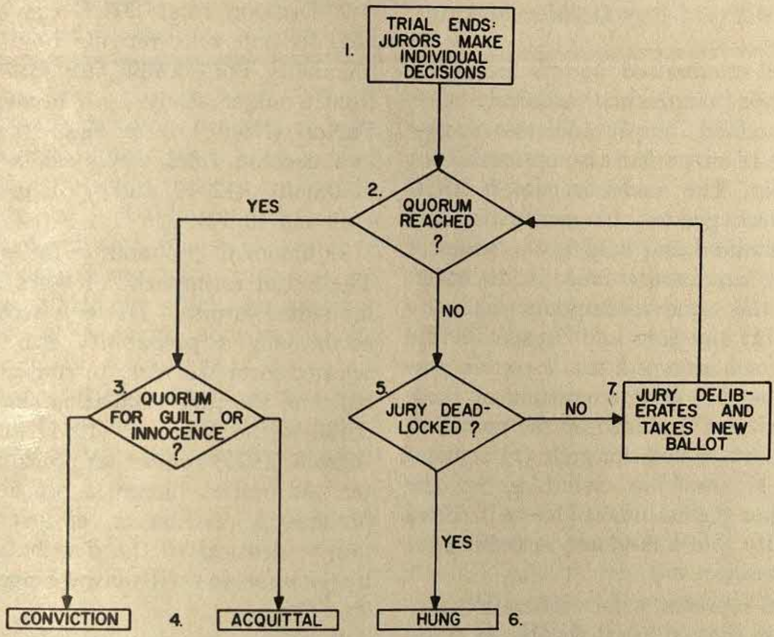

Figure 6. Flowchart summary of our model for jury decision making.

Grofman, 1976; Kerr et al., 1976; Grofman & Hamilton, Note 4).

The binomial model that we have presented avoids some of these problems by introducing more plausible assumptions about the weight of trial evidence and uses a decision scheme approach to determine the distribution of final verdicts. However, its characterization of the deliberation process is still rather barren.

For the present we conclude that the mathematical models built around the binomial theorem are quite adequate for dealing descriptively (and to a lesser extent, predictively) with the relationship between jury size and initial ballot distributions. However, these models are not yet adequate for analysis of jury verdicts. Until we have better knowledge of the actual deliberation process (theoreticians almost universally lament the paucity of relevant data) and this knowledge has been incorporated into the mathematical models, we should be cautious about accepting existing specifications or estimates of the following parameters: the accuracy of juror assessments of guilt and innocence, the prior probabilities of defendants' convictability, the accuracy of jury verdicts, decision rules that maximize juror satisfaction and performance, and the implications of changes in jury size.

We do not mean to imply that these parameters or even the deliberation processes cannot be mathematically modeled, for we are confident that with better and more extensive data, adequate mathematical models can be specified that will provide reliable estimates of the parameters of interest.

In the remainder of this article we summarize the results of our efforts to develop a multiparameter computer model of the deliberation process (the model is presented in detail in Penrod & Hastie, Note 6) that produces output that fits empirical data at a number of critical points (including, but not limited to, reversal and hanging rates). One major advantage of the computer modeling approach is that it allows analysis of the dynamic aspects of the jury decision-making process (i.e., the computer model can easily represent the process by which a jury moves from an initial vote distribution to a final verdict). Furthermore, the simulation method, although compatible with mathematical models, is more flexible in its ability to represent complex hypotheses about juror and jury behavior (e.g., Abelson, 1968).

Computer Model of Jury Decision Making

The model summarized here is somewhat broader in scope than the mathematical models we have examined, but it addresses similar issues and rests on similar assumptions about juror behavior. The model is named DICE after the Greek goddess frequently depicted wearing a blindfold and holding the scales of justice in one hand and a sword in the other. It rests on the same assumptions made by Walbert (1971) and Saks and Ostrom (1975): that at the conclusion of a trial a certain proportion of the jury pool (consisting of those jurors who are not excluded by the voir dire) will be prepared to vote for guilt (p) or innocence ($1 - p$) (or in a civil case, for the plaintiff [p] or the defendant [$1 - p$]). Thus, the probability that a randomly selected juror will vote to convict is p.

The model represents the deliberation process in a form that makes it possible to determine the probability that a randomly selected jury of size n, drawn from a pool in which a specified proportion of the jurors will vote to convict (p), and using any specified decision rule question (q) will produce a conviction, an acquittal, or will hang. Furthermore, the model represents the deliberation process in such a way that it is possible to determine the verdict probabilities for any potential first ballot alignment of votes. In the model decision making is largely characterized by majority persuasion, but in a few cases initial majorities fail to prevail in the deliberations and are either reversed (persuaded by the minority) or do not reach a quorum and hang. Similarly (depending on the case), juries who initially divide evenly sometimes reach verdicts and sometimes hang. Hung juries result when juries fail to attain quorums after extended deliberation. Figure 6 is a simplified representation of the deliberation process embodied in the model, but it does capture the basic structure of DICE.

Parameters

DICE is based on six major parameters:

1. Jury size: Although DICE can operate with any jury size, simulations have concentrated on 6- and 12-member juries.

2. Decision rule: DICE can operate with any decision rule, ranging from majority to unanimity. For example, in modeling the results from a major study by Padawer-Singer and Barton (Note 1), the simulations used the two decision rules employed in that study: unanimity (12/12 and 6/6) and five sixths (5/6 and 10/12).

3. Binomial probability for guilty votes: The initial assignment of votes to simulated individual jurors in DICE is accomplished by establishing a probability that a randomly selected juror will vote to convict on the first ballot of the jury simulation. This parameter parallels the Walbert (1971) and Saks and Ostrom (1975) conviction probability parameter. An initial binomial probability of .47 produces a distribution of first ballot votes nearly identical to the distribution produced by the jurors in the Padawer-Singer and Barton study.

By using a random number generator and the binomial value, all the jurors in a simulation are assigned an initial verdict preference (Step 1).

4. Transition probability function: Several methods of modeling the persuasion/deliberation process have already been noted; Walbert (1971) assumed simple majority persuasion and Davis (1973) offered a wide range of decision schemes. In contrast with these models, which make no attempt to model or explain the deliberation processes that occur between the first and last ballots, DICE follows an alternative approach proposed by Rothschild, Klevorick, and McNeil (Note 7). They have suggested that the deliberation process can be modeled as a continuous-time, birth-and-death Markov process in which the probability that the number of votes for conviction (or acquittal) will increase by one from Time 1 to Time 2 is equal to the proportion of jurors who voted to convict (or acquit) at Time 1. A similar approach has been adopted by Stasser and Davis (1977) and Davis (1978). Experimentation with various transition functions has shown that a function exhibiting a group momentum effect best fits the available empirical data (Penrod & Hastie, Note 6). The transition functions used in DICE are shown in Figure 7. Curve A in Figure 7 shows the probability that a coalition of any size

(from 0–12 in a 12-member jury) will remain intact (i.e., none of the coalition members will change their verdict preference) from one ballot (or time period) to the next. Curve B displays the corresponding probability that individual jurors will not change their verdict preference—the probability values are the *i*th roots of the group probabilities. Briefly, the group transition function (Curve A) captures the following phenomenon: In juries that are roughly equal in size (in which the majority has no more than eight adherents), the majority's persuasive advantage is slight; but as the majority coalition grows in size the probability that it will continue to grow increases exponentially, and single holdouts have a very low probability of not joining the majority (the probability of not changing on any one ballot is .183 for the lone holdout). Readers familiar with early conformity studies (e.g., Asch, 1951; Sherif, 1935) will probably note that these characteristics of the transition function are consistent with conformity research findings. More direct empirical confirmation of the group size effect can be found in research by Godwin and Restle (1974).

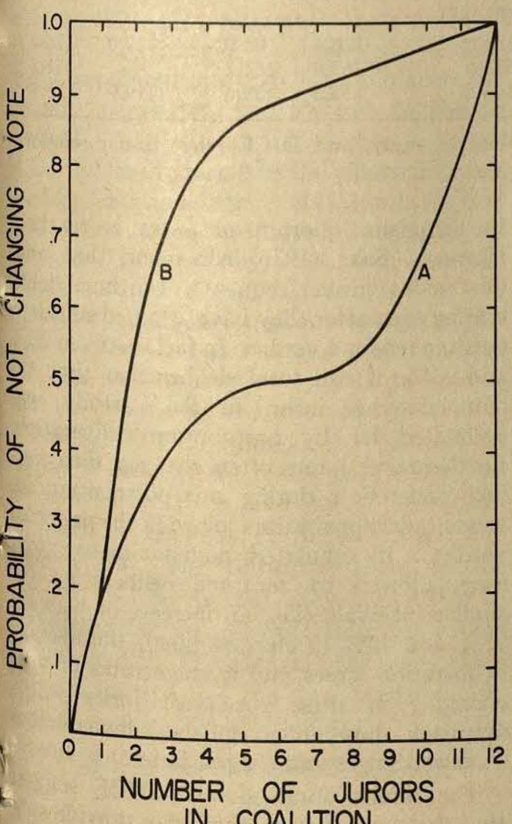

Figure 7. The two functions summarize vote-changing behavior of computer-simulated jurors as a function of coalition size. (Curve A presents the probability that no juror in a coalition of specified size will change votes, and Curve B presents the probability that an individual juror in a coalition will not change votes.)

5. Individual differences: Padawer-Singer and Barton (Note 1) reported that jurors in juries who ultimately reached a verdict were three times more likely to change their verdict preference during deliberation than jurors in juries who hung. This result and other similar results (e.g., the sex difference in change rates in the Kerr et al., 1976, study and the Davis, Kerr, Stasser, Meek, & Holt, 1977, rape case studies) indicate that some jurors are more susceptible to group persuasion than are other jurors. In DICE all jurors are assigned individual *persuasion resistance scores* that reflect these individual differences.

6. Maximum number of ballots: Not all juries reach a verdict; often members feel that they can no longer make progress toward a verdict because individual jurors are entrenched in their preferred verdict. To simulate hung juries DICE sets a limit on the number of ballots that a jury may take.

Evaluative Criteria

The Padawer-Singer and Barton (Note 1) study provides the widest range of data available on jury deliberations and specifically allows us to test DICE's operation with four different criteria: (a) the distribution of jury verdicts (convictions, acquittals, and hung juries); (b) the number of reversals of initial majorities, that is, juries in which a majority of members initially prefer conviction (acquittal) but the jury ultimately renders a verdict for acquittal (conviction); (c) the difference in the rate at which jurors in verdict-reaching juries change their verdict preferences and the rate at which jurors in juries who ultimately hang change their verdict preferences; and (d) the mean and variance in deliberation times for juries who convict, acquit, and hang.

Table 8
Summary of Simulation Results

	12-member jury				6-member jury			
	Unanimous		Nonunanimous		Unanimous		Nonunanimous	
Type of jury	PSB	DICE	PSB	DICE	PSB	DICE	PSB	DICE
				Verdict				
Guilty	8	7.53	9	7.53	8	7.71	9	7.79
Innocent	10	10.70	9	10.70	11	9.99	14	10.13
Hung	5	4.76	5	4.76	4	5.3	0	5.08
				Reversal of majority				
All juries	2	.8	4	.8	1	.3	2	.3
				% of jurors who changed votes				
Verdict juries	34.0	38.4	26.1	23.0	24.6	31.6	28.3	14.9
Hung juries	11.7	15.1	8.4	15.1	8.3	9.6	—	9.6
				Deliberation time				
Verdict juries	169.3	168.0	177.7	134.6	126.4	104.9	119.0	76.9
Hung juries	327.1	322.6	286.7	322.6	253.0	251.2	—	251.2
All juries	203.6	200.9	201.4	173.6	153.3	138.6	119.9	115.4

Note. PSB refers to Padawer-Singer and Barton's (Note 1) study, and DICE refers to our computer model of jury decision making.

Simulation Results

Table 8 summarizes the results of simulations of Padawer-Singer and Barton's 6- and 12-member juries, who used unanimous and five-sixths decision rules, and compares results produced by the actual juries and those obtained from the DICE simulations. Briefly, the distribution of verdicts is quite satisfactory—the poorest fit is in the 6-member, nonunanimous condition, in which none of the actual juries hung. Without exception the simulation juries produced lower reversal rates than the actual juries. This result suggests that the transition probabilities for juries of nearly equal sizes are probably flatter than is reflected in Curve B of Figure 7.

The rate of vote changing in simulated juries is very close to the empirical rate for unanimous juries, but is too low for nonunanimous juries who reach a verdict. Similarly, the average deliberation times for simulated and actual juries are very close for unanimous juries, but the simulated juries produce lower deliberation times in the nonunanimous conditions. At present, DICE renders a verdict as soon as the requisite quorum of votes is reached. However, Saks (1977) has found that nonunanimous juries frequently continue deliberating even after they have attained sufficient votes to render a verdict. In fact, between 20% and 31% of the total deliberation time for nonunanimous juries in Sak's study was accounted for by postquorum deliberation. Furthermore, jurors often changed their verdict preferences during this postquorum interval (additional jurors joined in the preferred verdict). If simulated nonunanimous juries were allowed to continue deliberating for similar intervals (i.e., an increase of between 25% and 40% in elapsed time), the average deliberation times and average rates of vote changing in these simulated juries would approach those found in the nonunanimous Padawer-Singer and Barton juries.

The results obtained with DICE suggest that the simulation method may provide substantial insights into the deliberation process by revealing the relationship between group size and persuasion and by providing a method for assessing the relative impact of individual differences on the persuasion process.

The simulation approach can serve as a useful complement to the mathematical models discussed earlier. DICE provides an alternative method for exploring the implicit decision rules that have been studied by Davis and his colleagues and has the advantage of making explicit and testable assumptions about events that occur between the first ballot and final verdicts. The aspect of the deliberation process that most closely approximates Davis's implicit rule is embodied in the transition function and can be summarized by saying that a majority's persuasiveness increases exponentially as the size of the majority increases. This general rule is likely to prevail across juries and cases, but the model will no doubt require modification when a case produces unusual individual reactions (e.g., DICE has produced excellent fits to the Davis, Kerr, Stasser, Meek, & Holt, 1977, rape data when the differential rates of vote changing by males and females are incorporated into DICE's individual differences parameter (see Penrod & Hastie, Note 6).

DICE also complements the binomial models used by Saks and Ostrom (1975) and Walbert (1971), insofar as the initial distribution of votes in DICE is produced by a binomial function. Furthermore, DICE avoids Walbert's simplistic assumptions about majority persuasion effects and uses a number of criteria to evaluate the assumptions about persuasion that are implicit in the transition function.

Finally, DICE promises to provide an empirical basis for the mathematical analyses of juror error rates and juror satisfaction proposed by Grofman (1976) and Nagel and Neef (1975). The principal defect of the existing analyses is that they are unable to make a satisfactory transition from first ballots to final verdicts. DICE makes the relationship between initial votes and final verdicts quite explicit and therefore provides a basis for extending the existing mathematical models.

Review and Conceptual Analysis of the Employee Turnover Process

W. H. Mobley, R. W. Griffeth, H. H. Hand, and B. M. Meglino
Center for Management and Organizational Research
University of South Carolina

Research on employee turnover since the Porter and Steers analysis of the literature reveals that age, tenure, overall satisfaction, job content, intentions to remain on the job, and commitment are consistently and negatively related to turnover. Generally, however, less than 20% of the variance in turnover is explained. Lack of a clear conceptual model, failure to consider available job alternatives, insufficient multivariate research, and infrequent longitudinal studies are identified as factors precluding a better understanding of the psychology of the employee turnover process. A conceptual model is presented that suggests a need to distinguish between satisfaction (present oriented) and attraction/expected utility (future oriented) for both the present role and alternative roles, a need to consider nonwork values and nonwork consequences of turnover behavior as well as contractual constraints, and a potential mechanism for integrating aggregate-level research findings into an individual-level model of the turnover process.

Employee withdrawal, in the form of turnover, has sustained the interest of personnel researchers, behavioral scientists, and management practitioners. At the macro level, economists and personnel researchers have demonstrated the relationship between turnover rates and the aggregate level of economic activity, employment levels, and vacancy levels (see, e.g., Armknecht & Early, 1972; Forrest, Cummings, & Johnson, 1977; Price, 1977; Woodward, 1975–1976). At the micro level, behavioral research has established a consistent, although generally weak, correlation between job dissatisfaction and turnover (Brayfield & Crockett, 1955; Locke, 1976; Porter & Steers, 1973; Vroom, 1964; Herzberg, Mausner, Peterson, & Capwell, Note 1). While the economic and job dissatisfaction contributions to turnover are well established, they are conceptually simplistic and empirically deficient bases for understanding the employee turnover process.

Recently, a number of authors (Forrest et al., 1977; Locke, 1976; Mobley, 1977; Porter & Steers, 1973; Price, 1977) have advocated abandoning further replication of bivariate correlates of turnover, particularly job dissatisfaction, in favor of well-developed conceptual models of the turnover process. Such a model is one objective of this article.

Employee turnover is a behavior of interest to many disciplines and is subject to analysis and discussion at many levels of discourse. The approach taken in this article is basically psychological and rests on the belief that turnover is an individual choice behavior. Thus, the individual is the primary unit of analysis. Selecting the individual as the unit of analysis does not mean that turnover research at the unit, organizational, or other aggregate level is not of value and interest. However, to conclude that such studies clarify the individual turnover decision process may be tantamount to what Robinson

(1950) has termed the *ecological fallacy*. For example, the relationship between aggregate unemployment levels and turnover rates, although well established (see, e.g., Armknecht & Early, 1972; Price, 1977; Woodward, 1975–1976) adds little to understanding individual turnover decisions. A linking mechanism is needed that considers the individuals's perception and evaluation of available alternatives relative to the present position.

At the individual level, satisfaction is the most frequently studied psychological variable thought to be related to turnover. However, the satisfaction–turnover relationship, although consistent, usually accounts for less than 16% of the variance in turnover (Locke, 1976; Porter & Steers, 1973). It is apparent that models of the employee turnover process must move beyond satisfaction as the sole explanatory variable.

Recently, the constructs of organizational commitment (Porter, Crampon, & Smith, 1976; Porter, Steers, Mowday, & Boulian, 1974; Steers, 1977), organizational attachment (Koch & Steers, 1978), role attachment (Graen, 1976; Graen & Ginsburgh, 1977), and behavioral intentions (Kraut, 1975; Mobley, 1977; Newman, 1974) have been offered as explanatory concepts in the turnover process. However, the conceptual and empirical identity of these concepts and their interrelationships have not always been clear. An additional objective of the present article is to attempt to clarify and integrate these concepts into a general model of the individual employee turnover process.

A third objective of this article is to update earlier reviews of the literature. The last major review of turnover from the individual perspective was that of Porter and Steers (1973). For somewhat more limited reviews of certain aspects of turnover, see Goodman, Salipante, and Paransky (1973) on the hardcore unemployed and retention and Pettman's (1973) partial review of the March and Simon (1958) model. More recently, Price (1977), a sociologist, has published a significant book that seeks to codify the turnover literature from a variety of disciplines and cultures. The Price work contains a number of references generally not

Table 1 *(continued)*

Factor	Population	*N*	Relation to turnover
Personality Hines (1973)	New Zealand Entrepreneurs Engineers Accountants Middle managers	 80 74 68 93	Entrepreneurs had higher need for achievement and lower turnover rate than other occupational groups; individuals with higher need for achievement had higher turnover in nonentrepreneur groups
Distance migrated Marsh & Mannari (1977)	Japanese electrical company employees	1,033	$r = -.12^{**}$; employees who grew up near the factory had higher turnover
Number of previous jobs Marsh & Mannari (1977)	Japanese electrical company employees	1,033	*ns*

included in the psychological and management turnover literature cited in the United States; however, it does not deal with post-1974 research and is incomplete in its coverage of the psychological and management literature on employee turnover. Forrest et al. (1977) also recently presented a partial review of the turnover literature. However, the latter review, which deals with a broader spectrum of organizational participation behaviors, contains no post-1973 research and has a conceptual rather than an empirical emphasis. The Forrest et al. model is discussed in a later section of this article.

In summary, the major objectives of this article are (a) to update the last major reviews and analyses of the turnover literature, (b) to attempt to clarify the distinctions among various constructs that have recently been suggested as explanatory variables in the turnover process, (c) to develop a conceptual model of the individual-level employee turnover process that is consistent with the research literature, and (d) to suggest areas of further research.

This article focuses on voluntary, that is, self-initiated, turnover rather than on organization-initiated terminations. This distinction, discussed in a subsequent section, is not always made clear in specific research studies. Additionally, this article does not deal with absenteeism. Whether absenteeism is best thought of as having no consistent relationship to turnover (March & Simon, 1958), as a precursor of turnover (Herzberg et al., Note 1), or as an alternative form of withdrawal behavior (Hill & Trist, 1955; Rice & Trist, 1952) is an important research question (Burke & Wilcox, 1972), but is beyond the scope of the present article.

Update of Turnover Analyses and Reviews

The last major reviews of the turnover literature were by Porter and Steers (1973) and Price (1977). This section summarizes the recent research not included in these reviews and offers the conclusions of the authors of this article. A subsequent section summarizes and integrates the results of this and the two previous reviews. Although no taxonomic schema is entirely satisfactory, the research summary is divided into the following sections: (a) individual demographic and personal variables, (b) overall satisfaction, (c) organizational and work environment factors, (d) job content factors, (e) external environment factors, (f) occupational groupings, (g) recently developed constructs, and (h) multivariate studies. Most studies reviewed take a bivariate approach to turnover, but this emphasis is reflective of the current literature rather than of the present authors' belief in the relative merit of this approach.

Individual Demographic and Personal Factors

Included in this category are age, tenure, sex, family responsibilities, education, personality, other personal considerations, and weighted application blanks. Table 1 summarizes recent research on these variables, which were not included in the Porter and Steers or Price reviews.

Age. Recent research, with the exception of Hellriegel and White (1973) who reported no differences, indicates a negative relationship between age and turnover. However, the amount of variance explained is less than 7%. One should note that since age is correlated with many other variables, it alone contributes little to the understanding of turnover behavior. As is noted later, a conceptual model and multivariate studies are required to adequately comprehend the psychology of the turnover process. This observation also applies to each variable discussed below.

Tenure. Three recent studies, cited in Table 1, showed a negative relationship between tenure and turnover. Mangione (Note 2) concluded on the basis of a multivariate study (see Table 12 for a summary of multivariate studies) that length of service is one of the best single predictors of turnover.

Sex. Of the two studies relating an individual's sex to turnover, Marsh and Mannari (1977) observed that female Japanese manufacturing employees had higher turnover than males. Mangione (Note 2) found no relationship.

Family responsibilities. Three of the four studies summarized in Table 1 indicate that family responsibility, including marital status, is associated with decreased turnover.

Education. Of the recent studies dealing with education, one found that female credit union employees with higher education had lower tenure (Federico, Federico, & Lundquist, 1976), whereas Mangione (Note 2) and Hellriegel and White (1973) discovered no differences. Lack of variance in education in studies such as Hellriegel and White's, which used certified public accountants, precludes adequate evaluation of the role of education.

Weighted application blanks. Weighted application blanks use a procedure for weighting information on an employment application form so as to predict some aspect of job performance, including turnover. Schwab and Oliver (1974) have raised serious questions regarding the utility of weighted application blanks for predicting turnover. In four samples, they found that validities shrunk below statistical significance upon cross-validation. However, in two recent studies Cascio (1976) and Lee and Booth (1974) reported significant relationships that were cross-validated. The utility of weighted application blanks for employee selection continues to require situation-specific validation (and regular cross-validation), and alone they offer little contribution to understanding the psychology of the turnover process.

Other personal variables. Table 1 cites other studies that dealt with personality, distance migrated, and number of previous jobs. Because the number of studies is small, no generalizations are possible.

Overall Job Satisfaction and Turnover

Studies involving overall job satisfaction are summarized in Table 2. With one exception (Koch & Steers, 1978), these studies indicate a negative relationship between overall satisfaction and turnover. It is important to note, however, that the amount of variance accounted for is consistently less than 14%. As noted in subsequent sections, when satisfaction is included in multiple regressions with variables such as intentions and com-

Table 2
Studies of Relation of Overall Job Satisfaction to Turnover

Study	Population	N	Relation to turnover
Ilgen & Dugoni (Note 3)	Retail clerks; baggers	117	$r = -.31^{**}$ on Minnesota Satisfaction Questionnaire

Table 3
Studies of Relations Between Pay–Promotion and Turnover

Factor	Population	N	Relation to turnover
Salary, actual and expected			
Federico, Federico, & Lundquist (1976)	Credit union females	96	Higher salary associated with longer tenure (salary strictly performance based); the greater the difference between expected and actual, the shorter the tenure; the higher the expectations, the lower the tenure
Salary increases			
Hellriegel & White (1973)	Certified public accountants	349	Turnovers reported 20% increases in pay on new job
Satisfaction with pay			
Hellriegel & White (1973)	Certified public accountants	349	Turnovers more negative than nonturnovers on attitudes toward pay policies and comparability of salary (significance levels not reported)
Koch & Steers (1978)	Nonmanagement entry-level public agency employees	77	*ns*
Kraut (1975)	Salesmen	911	*ns*
Mangione (Note 2)	Institute for Social Research diverse occupational sample	295	$r = -.16^{*}$
Mobley, Horner, & Hollingsworth (1978)	Hospital employees	203	*ns*
Newman (1974)	Nursing home employees	108	*ns*
Waters, Roach, & Waters (1976)	Female insurance company clerical	105	*ns*
Satisfaction with promotion, advancement			
Hellriegel & White (1973)	Certified public accountants	349	Turnovers more negative about opportunities than nonturnovers (significance levels not reported)
Koch & Steers (1978)	Nonmanagement entry-level public agency employees	77	*ns*
Kraut (1975)	Salesmen	911	*ns*
Mobley et al. (1978)	Hospital employees	203	*ns*
Newman (1974)	Nursing home employees	108	*ns*
Waters et al. (1976)	Female insurance company clerical	105	*ns*
Perceived chances of promotion			
Marsh & Mannari (1977)	Japanese electrical company employees	1,033	$r = -.22^{*}$; poorer perceived chances of promotion had higher turnover

* $p < .01$.

Table 4
Studies of Relations Between Supervision and Turnover

Factor	Population	N	Relation to turnover
Satisfaction with supervision			
Hellriegel & White (1973)	Certified public accountants	349	Turnovers had significantly less favorable attitudes (few significance tests reported)
Ilgen & Dugoni (Note 3)	Retail clerks	117	$r = -.23^*$
Koch & Steers (1978)	Nonmanagement entry-level public agency employees	77	*ns*
Mobley, Horner, & Hollingsworth (1978)	Hospital employees	203	*ns*
Newman (1974)	Nursing home employees	108	*ns*
Waters, Roach, & Waters (1976)	Insurance company clerical	105	*ns*
Leader acceptance			
Dansereau, Cashman, & Graen (1974)	Managers	354	$r = -.11^*$ (and moderated by expectancy of finding comparable alternative, $r = -.21^*$ for high-expectancy group, $n = 98$)
Graen & Ginsburgh (1977)	University service employees	89	Significant main effect ($p < .024$) with resignation at 24 months; leader acceptance defined in terms of leader's flexibility in changing employee job and chances of leader using his or her power to help employees solve work problems

$^* p < .05$.

mitment, its effect on turnover may become nonsignificant (Marsh & Mannari, 1977; Mobley, Horner, & Hollingsworth, 1978).

Organizational and Work Environment Factors

Pay and promotion. Research dealing with pay and promotion is summarized in Table 3. Federico et al. (1976) found that higher salary was associated with longer tenure, whereas higher salary and the difference between expected and actual salary were associated with shorter tenure. Mangione (Note 2) found a significant negative correlation between pay satisfaction and turnover. Hellriegel and White (1973) discovered that "leavers" had more negative attitudes toward pay than "stayers" and also reported significant increases in pay on their new jobs. Evidence from five other recent studies suggests a lack of relationship between pay satisfaction and turnover.

Also evident in Table 3 is the general lack of relationship between satisfaction with promotion and turnover, although Hellriegel and White did find that leavers had more negative attitudes toward promotion than stayers. Marsh and Mannari (1977) reported a correlation of −.22 between perceived chances of promotion and turnover.

Supervision. Table 4 summarizes recent studies relating satisfaction with supervision to turnover. In four of the studies a nonsignificant relationship between satisfaction with supervision and turnover was found. Hellriegel and White (1973) and Ilgen and Dugoni (Note 3) found a significant negative relationship. The study by Graen and Ginsburgh (1977) is of particular interest. Here, leadership was significantly associated with turnover. The leadership variable, however, was not satisfaction with supervision but specific aspects of the leader–member exchange. Contrasted with the conclusions of recent studies using satisfaction with supervision as the independent variable, the Graen and Ginsburgh results suggest the need for more detailed study of the leader–member exchange rather than reliance on generalized supervision affect measures.

Table 5
Studies of Relations Among Group Cohesiveness, Teamwork, and Satisfaction with Co-Workers

Factor	Population	*N*	Relation to turnover
Co-Workers, Teamwork, Team Effectiveness, and Cohesiveness			
Hellriegel & White (1973)	Certified public accountants	349	"Generally" more negative for turnovers (few significance tests reported)
Ilgen & Dugoni (Note 3)	Retail clerks	117	*ns* (co-workers)
Koch & Steers (1978)	Nonmanagement entry-level public agency employees	77	$r = -.21^*$ (co-workers)
Kraut (1975)	Salesmen	911	*ns* (teamwork)

Self-Perception of task-relevant abilities			
Ekpo-Ufot (1976)	Auto assemblers	123	$r = -.27^{**}$ (sum of 6 measures); higher turnover associated with lower self-perceived abilities
Coping behavior			
Ilgen & Dugoni (Note 3)	Retail clerks	117	*ns* (self-evaluation of coping with critical incidents)
Perceived performance			
Marsh & Mannari (1977)	Japanese electrical company employees	1,033	$r = -.14$; poorer performers had higher turnover

$^{*}p < .05$. $^{**}p < .01$.

Overall, recent studies offer moderate support for the negative relationship between satisfaction with supervision and turnover. However, the number of studies finding no significant relationship between these variables indicates the need to more closely examine the nature of leadership measures, to conduct more microanalyses of the leader–member exchange, and to assess the contribution of supervision in multivariate designs that consider other salient variables.

Peer group relations. Research on peer relations and turnover is shown in Table 5. In seven of the nine studies, no significant results were reported. Koch and Steers (1978) found a significant correlation between satisfaction with co-workers and turnover, but only 4% of the variance was explained. The studies summarized in Table 5 do not support the generalization of a strong relationship between group relations and turnover. Individual differences in variables such as need for affiliation, the role of other variables, for example, required task interaction and external job alternatives and the method of measuring group relations contribute to the difficulty in explicating these findings.

Other variables. Table 6 describes recent studies dealing with a variety of other organizational and work environment factors. Both Hellriegel and White (1973) and Marsh and Mannari (1977) found a negative relationship between preceived status and turnover. This status may have come, in part, from the work role or from organizational affiliation. Knowledge of organizational procedures and perceptions of control processes were each shown to be negatively related to turnover. In three separate studies, role pressures, climate, and satisfaction with the company were not significantly related to turnover. Ilgen and Dugoni (Note 3) found a significant negative correlation between satisfaction with hours of work and turnover among retail clerks. Mangione (Note 2) discovered a significant negative correlation between resource adequacy and turnover.

Job Content Factors

Recently job content has become one of the more active areas of industrial–organiza-

tional research. A number of studies in this area have employed turnover as a criterion. Inspection of the recent studies shown in Table 7 indicates that job content factors are significantly related to turnover. Satisfaction with work itself exhibits a uniform negative correlation with turnover, although the amount of variance explained is consistently less than 16%.

Additional studies indicate that the perceived intrinsic value of work, intrinsic motivation, and intrinsic satisfaction are all significantly and negatively related to turnover. Graen, Orris, and Johnson (1973) and Graen and Ginsburgh (1977) demonstrated that role orientation, defined as the perceived relevance of the job for the worker's career, was significantly related to turnover.

In a particularly interesting study, because it took a somewhat different approach, Ekpo-Ufot (1976) found that self-perception of task-relevant abilities was significantly and negatively associated with auto assembler turnover.

External Environment

The probable role of the availability of alternative jobs in employee turnover has long been recognized; see, for example, March and Simon (1958). Economists and sociologists have documented the aggregate-level relationship between economic indicators such as employment levels or job vacancy rates and turnover rates (Price, 1977). However, research on individual-level turnover has infrequently assessed perceived alternatives (Forrest et al., 1977; Locke, 1976). Conceptually, the perception and evaluation of alternatives seems to be a crucial variable in the individual turnover process. Empirically, assessment of the relationship between turnover and personal, organizational, job content, or other variables is inexorably bound to consideration of the perception and evaluation of alternatives.

Table 8 summarizes the limited amount of recent research dealing with alternatives. Woodward (1975–1976) reaffirmed the aggregate-level negative relationship between unemployment and turnover and the positive

Table 8
Studies of the Relation Between External Alternatives and Turnover

Factor	Population	*N*	Relation to turnover
Economic conditions Woodward (1975–1976)	British chemical company	not reported	Local labor market: unemployment, $R^2 = .34$; unfilled vacancies, $R^2 = .66$; unemployment, vacancy, and a seasonal dummy, $R^2 = .83$
Expectancy of finding alternative Dansereau, Cashman, & Graen (1974)	Office workers Managers	222 354	In both samples, the perceived expectancy of finding a comparable job moderated the correlation between attitude and turnover (office workers, $r = -.18^{**}$; managers, $r = -.11^{*}$)
Mobley, Horner, & Hollingsworth (1978)	Hospital employees	203	Expectancy of finding an acceptable alternative significantly correlated with intention to quit ($r = .15^{*}$); intention to search correlated significantly with turnover ($r = .29^{**}$)

$^{*}p < .05$. $^{**}p < .01$.

relationship between unfilled vacancies and turnover rates. At the individual level, Dansereau, Cashman, and Graen (1974) found that the expectancy of finding an alternative job moderated the correlations between attitude and turnover. Mobley et al., (1978) found that expectancy of finding an acceptable alternative position was significantly and positively related to intention to quit but not to actual quitting, although intention to quit was significantly and positively related to turnover. It is evident that much additional research is required to explicate the role of perception and evaluation of alternatives in the individual turnover process.

Occupational Groupings

Price (1977) reviewed research on occupational characteristics and found moderate support for the proposition that unskilled blue-collar workers have higher turnover than white-collar workers. He found only weak support for the propositions that nonmanagers have higher turnover than managers, that nongovernment employees have higher turnover than government employees, and that higher professionalism is associated with higher turnover.

Since most individual-level turnover studies are carried out within occupational groupings, the present review adds little to Price's analysis. It is apparent, however, that any complete model of individual turnover behavior should be able to account for differences in turnover among occupational groupings. The perception and evaluation of alternatives is one obvious link between the two levels of analysis. A second is exemplified in the research of Herman and Hulin (1972) and Herman, Dunham, and Hulin (1975), which demonstrated that organizational variables such as position level may be better predictors of behavior than demographic or personality variables. The frame of reference provided by position level may influence values, perceptions, and expectations, thus linking organizational variables with individual behavior.

Recently Explored Variables and Processes

Since the Porter and Steers (1973) review, interest has developed in a variety of additional variables, constructs, and processes, including behavioral intentions, organizational commitment, realistic expectations, and the centrality of work values.

Behavioral intentions. The Fishbein (1967) and Fishbein and Ajzen (1975) model of the relationships among beliefs, attitudes, intentions, and behaviors emphasizes the role of intentions in understanding the link between attitudes and behavior. The Locke (1968) model of task motivation also conceives of intention as an immediate precursor of behavior. Drawing on these and other related theoretical models, a number of recent studies have assessed the role of intentions in predicting and understanding turnover. Table 9 summarizes these studies.

It is evident from these studies that behavioral intentions to stay or leave are consistently related to turnover behavior. It is also evident that this relationship generally accounts for more variance in turnover than does the satisfaction–turnover relationship. Conceptually this appears appropriate, since satisfaction is an affective or emotional response, whereas intentions are statements regarding the specific behavior of interest, in this case, turnover. It is possible, as Mobley et al. (1978) suggested, that intentions also capture the individual's perception and evaluation of alternatives.
